THIS

NEW AMERICAN EDITION OF GRAY'S ANATOMY

IS DEDICATED TO

WILLIAM W. KEEN, M.D., LL.D., HON. F.R.C.S. [ENG. AND EDIN.]
THE DISTINGUISHED PROFESSOR OF SURGERY IN JEFFERSON MEDICAL COLLEGE
AS AN EVIDENCE OF
THE ADMIRATION, THE AFFECTION AND THE GRATITUDE OF HIS COLLEAGUE

AND FORMER ASSISTANT

THE EDITOR
PREFACE.

In this revision of Gray's Anatomy, the Editor has endeavored to reflect the development of the subject since the appearance of the last edition, and has sought to accomplish this without sacrificing those practical and didactic characteristics that have ever been the most notable features of the book. Radical innovations were undesirable, and original exposition was neither desirable nor possible. The Editor is responsible for some eliminations, many alterations, and a great number of additions; and it has been deemed unwise even to attempt to designate, by brackets or any other device, so great a number of changes and additions.

In order that its pages might represent the world's best knowledge, American, English, French, and German text-books, monographs, and journal-articles have been freely consulted. In using statements from these numerous sources, the aim has been to give, in every instance, proper credit to the author. If, in some cases, this has not been done, the failure is the result of accident, and never of design.

Among the many works thus utilized may be mentioned the three composite treatises edited by Gerrish, Cunningham, and Morris, respectively; Poirier and Charpy, Testut, Spalteholz (which has recently been translated into English and edited by Professor Barker); Hughes's Practical Anatomy, edited and completed by Keith; McClellan's Regional Anatomy; Deaver's Surgical Anatomy; Treves's Applied Anatomy; Owens's Manual of Anatomy; Eisendrath's Clinical Anatomy; Byron Robinson, on the Peritoneum; and the text-books of Quain and MacAllister. Special credit is due to the chapter on the “Lymphatics” in Poirier and Charpy (translated and edited by Leaf); to the admirable section on the “Nervous System,” written by Professor Cunningham in his text-book; and to Professor Santee’s extremely valuable monograph on the Anatomy of the Brain and Spinal Cord.

The Latin, new or international nomenclature has been introduced in parentheses, following the names still currently used in English-speaking countries. This system of coupling the current and the new names answers the needs of all students, and will facilitate the much-to-be-desired adoption of the new nomenclature. The Latin nomenclature was recommended by an international committee, was published by Wilhelm His, and has been generally accepted by anatomists. Owing to its accuracy and its simplicity, it seems destined eventually to succeed the older methods of designation; but in this country at least, the older nomenclature is still too firmly fixed to be entirely and suddenly abandoned.

Gray’s Anatomy has been noted for the extent and the elaborate nature of its illustrations. This new edition exceeds its predecessor in the number of engravings and in the use of colors. The series now aggregates over eleven hundred, of which about five hundred are new in this edition. Particular acknowledgment for originals is due to Spalteholz, Cunningham, Poirier and Charpy, Testut, Gerrish, Byron Robinson, and the Atlas of Human Anatomy by Carl Toldt, assisted by
A. D. Rosa (recently translated into English and edited by M. Eden Paul). The pictures taken from these various sources have been re-engraved, and in some instances have been modified.

In this edition the special articles on "Histology" and "Embryology," hitherto placed at the end of the book, have been eliminated. The extent, the importance, and the technical nature of these great subjects have led to the creation of special chairs for their teaching; and it seems desirable that the text-books used by the students should be those written by men devoted to these specialties. No single volume, in these days, can offer adequate instruction on anatomy, histology, and embryology; and to attempt it would be unwise. The bearings of histology and embryology upon anatomy are close and highly important. The Editor has set forth the essential points of these subjects when the elucidation of the text demanded it by means of résumés. For these, he has drawn chiefly upon the excellent sections in the previous edition of Gray (which were edited by Robert Howden), supplementing them from the Histology and Microscopic Anatomy by Szymonowicz (translated by John Bruce MacCallum), the text-book of Histology by Bohm and von Davidoff (edited by G. Carl Huber), and the text-book of Embryology by John Clement Heisler. The clear and instructive surgical notes of Mr. Pick have, of course, been retained; although, here and there, they have been modified or added to, in accordance with the views of the day. Because of an oversight the foot-notes, thirty-five in number, from page 49 to page 497 inclusive, are not credited to the Editors of the 15th English edition. Subsequent to page 497 proper credit is given for foot-notes from the English editors.

The Editor desires cordially to express his sense of indebtedness and gratitude to Dr. Howard Dehoney, Senior Assistant Demonstrator of Anatomy in the Jefferson Medical College, for his able and conscientious aid and collaboration. When a book has been edited many times by many men, the views and the style of the author are sure to be more or less obscured. The Editor of this edition hopes that Gray's Anatomy has not suffered too many things at his hands.

John Chalmers Da Costa.

Philadelphia, 1905.
HENRY GRAY died young, but left in his masterpiece imperishable evidence of his two-fold genius, on the one hand a profound capacity to grasp the structure of the human body, and on the other an equal insight into the mind and the best method of imparting knowledge. His work immediately attained its merited pre-eminence, a position which the many excellent treatises of the past fifty years have only rendered more conspicuous.

During this period frequent revisions have kept Gray always abreast of the active development of its subject. Among its editors it has numbered many of the ablest anatomists on both sides of the Atlantic. The services of Dr. Da Costa were sought by the Publishers by reason of his combined qualifications as an anatomist, a teacher and a surgeon. He has borne in mind the Author's original purpose, namely, to facilitate to the utmost the work of instructors and students, and to afford the physician and surgeon the assistance necessary in practice. He has revised every page, elaborating the text where necessary to cover the latest developments, and to ensure due proportion, and has greatly enriched the illustrations both in number and in the use of colors. The names of the parts are engraved directly upon them, a feature original with Gray and peculiar to his work. The advantage is obvious. Ample directions are given for dissection. The new nomenclature has been introduced in parentheses following the names still in common use, an arrangement preferable to either system alone. The book is thoroughly organized in its headings and with heavy type catchwords in the text, so that the student readily gains a knowledge of the parts in their anatomical dependence.

From the foregoing outline it is not difficult to appreciate the reasons for the fact often observed that Gray is the easiest work from which to teach, to learn, to prepare for examinations for collegiate degrees and state licenses, and to use for reference in the practice of medicine and surgery.

Grateful acknowledgment is made by the Publishers to Dr. William T. Eckley, Dr. D. Kerfoot Shute, Dr. E. C. Henry, Dr. William Keiller, Dr. A. Primrose, Dr. Samuel B. Childs, Dr. William D. Sumpter, Dr. William Perrin Nicolson, Dr. Charles L. Mix, Dr. L. F. Barker, Dr. Norman E. Jobes, Dr. John E. Hays, Dr. A. C. Pole, Dr. Isaac R. Trimble, Prof. J. P. McMurrich, Dr. Daniel La Ferte, Dr. Kenneth Gonsolus, Dr. George J. Gordon, Dr. Norman Driesbach, Dr. Charles A. Erdman, Dr. George H. Hoxie, Dr. Howard Hill, Prof. A. C. Eycleshymer, Dr. Peter Potter, Dr. Robert J. Terry, Dr. V. P. Blair, Dr. Joseph D. Craig, Dr. James A. Gibson, Dr. Abram T. Kerr, Dr. George M. Price, Dr. Josiah Meilbery, Dr. Louis D. Barbot, Dr. Elmer E. Francis, Dr. Samuel S. Briggs, Dr. Ira C. Chase, Dr. Henry C. Tinkham, Dr. William P. Mathews, Dr. William G. Doern, and many other eminent anatomists and teachers whose kindly criticisms and intelligent suggestions have aided so materially in bringing Gray to its present excellence.
CONTENTS.

DESCRIPTIVE AND SURGICAL ANATOMY.

OSTEOMETRY—THE SKELETON.

The Skeleton ........................................... 33

DESCRIPTIVE AND SURGICAL ANATOMY.

OSTEOMETRY — THE SKELETON.

THE entire skeleton in the adult consists of 200 distinct bones. These are:

<table>
<thead>
<tr>
<th>Bone Description</th>
<th>Number</th>
</tr>
</thead>
<tbody>

<tr>
<td><strong>Total</strong></td>
<td><strong>200</strong></td>
</tr>
</tbody>
</table>

In this enumeration the patellae are included as separate bones, but the smaller sesamoid bones and the ossicula auditus are not reckoned. The teeth belong to the tegumentary system. Different anatomists make different computations as to the number of bones in the skeleton. Some describe the skeleton as containing 206 distinct bones, adding the ossicles of the ear to the previously stated number. By adding the epipteric bones, the sphenoidal turbinal bones, the sesamoid bones, and others, the number may be greatly augmented.

Bones are divisible, according to their shape, into four classes: long, short, flat, and irregular.

**Long Bones.**—The long bones are found in the limbs, where they form a system of levers, which sustain the weight of the trunk and confer the power of locomotion. A long bone consists of a shaft and two extremities. The shaft is a hollow cylinder, contracted and narrowed to afford greater space for the bellies of the muscles; the walls consist of dense, compact tissue of great thickness in the middle, but becoming thinner toward the extremities; the spongy tissue is scanty, and the bone is hollowed out in its interior to form the medullary canal. The extremities are generally somewhat expanded for greater convenience of mutual connection, for the purpose of articulation, and to afford a broad surface for muscular attachment. Here the bone is made up of spongy tissue with only a thin coating of compact substance. The long bones are not straight, but curved, the curve generally taking place in two directions, thus affording greater strength to the bone. The bones belonging to this class are the clavicle, humerus, radius, ulna, femur, tibia, fibula, metacarpal and metatarsal bones, and the phalanges.

**Short Bones.**—Where a part of the skeleton is intended for strength and compactness, and its motion is at the same time slight and limited, it is divided into a number of small pieces united together by ligaments, and the separate bones are short and compressed, such as the bones of the carpus and tarsus. These bones, in their structure, are spongy throughout, excepting at their surface, where
there is a thin crust of compact substance. The patellae also, together with the other sesamoid bones, are by some regarded as short bones.

**Flat Bones.**—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, we find the osseous structure expanded into broad, flat plates, as is seen in the bones of the skull and the shoulder-blades. Flat bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones these layers of compact tissue are familiarly known as the *tables of the skull*; the outer table is thick and tough; the inner table is thinner, denser, and more brittle, and hence is termed the *vitreous table*. The intervening cancellous tissue is called the *diploe*. The flat bones are: the *occipital, parietal, frontal, nasal, lachrymal, vomer, scapula, os innominatum, sternum, ribs, and patella*.

**Irregular Bones.**—The irregular or mixed bones are such as, from their peculiar form, cannot be grouped under either of the preceding heads. Their structure is similar to that of other bones, consisting of a layer of compact tissue externally and of spongy, cancellous tissue within. The irregular bones are: the *vertebrae, sacrum, coccyx, temporal, sphenoid, ethmoid, malar, superior maxilla, inferior maxilla, palate, inferior turbinate, and hyoid*.

**Surfaces of Bones.**—If the surface of any bone is examined, certain eminences and depressions are seen, to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: *articular* and *non-articular*. Well-marked examples of articular eminences are found in the heads of the humerus and femur and of articular depressions in the glenoid cavity of the scapula and the acetabulum. Non-articular eminences are designated according to their form. Thus a broad, rough, uneven elevation is called a *tuberosity*; a small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a *spine*; a narrow, rough elevation, running some way along the surface, a *ridge, line, or crest*.

The non-articular depressions are also of very variable form, and are described as *fossae, grooves, furrows, fissures, notches, sulci*, etc. These non-articular eminences and depressions may receive blood-vessels, nerves, tendons, ligaments, or portions of organs, or may serve to increase the extent of surface for the *attachment* of ligaments and muscles. They are usually well marked in proportion to the muscular development of the subject.

A prominent process projecting from the surface of a bone which it has never been separate from or movable upon is termed an *apophysis* (from ἀπό-φυσις, an excrescence); but if such process is developed as a separate piece from the rest of the bone, to which it is afterward joined, it is termed an *epiphysis* (from ἐπί-φυσις, an accretion). The main part of the bone, or shaft, which is formed from the primary centre of ossification, is termed the *diaphysis*, and is separated, during growth, from the epiphysis by a layer of cartilage, at which growth in length of the bone takes place. Some bones are hollow and contain *sinuses*, which are spaces for air. *Canals or foramina* are channels or openings in bone through which nerves or vessels pass.

**Structure of Bone.**—Bone is a highly specialized form of connective tissue. In reality, it is white fibrous tissue, calcified and structurally modified until it becomes osseous tissue. Bone is not simply a crude mass resulting from the calcification of cartilage or fibrous tissue; it is a distinct tissue, of a definite structure, the constituent parts of which are arranged symmetrically. Its structure varies somewhat in different vertebrates.

---

1 Arquitectura del Aparato de Sustentación en los Vertebrados. Por el Dr. Saturnino García Hurtado. Our description applies to human bone.
There are two varieties of bone: dense or compact bone (substantia compacta), and cancellous, loose, or spongy bone (substantia spongiosa).

Compact Bone is dense, like ivory, and is always placed upon the exterior of bones. Even this apparently compact tissue is porous; it differs from cancellous bone in the greater density of its tissue and in the arrangement of its osseous plates into Haversian systems. Compact bone is surrounded by periosteum.

Cancellous Bone is found in the interior of bones. The name, which means lattice-work, indicates the structure, which consists of slender fibres and lamellae joined to form a reticulum, the small meshes of which are marrow-spaces.
spicules of cancellous bone contain lacunae and canaliculi, but no Haversian systems. In some regions the inner portion of the wall of a long bone, about the marrow-cavity, is composed of cancellous bone. Toward each extremity of the shaft the amount of cancellous tissue increases, the marrow-cavity diminishes in size, and the cancellous tissue is arranged in lines that approach each other toward the extremity, like the sides of an arch, and form a support for the epiphysis (Fig. 131). In the epiphysis the bone-plates are, as a rule, at right angles to the plane of the articular surface (the lines of greatest pressure); and they are bound together or strengthened by other bone-fibres, which are usually in correspondence with the planes of the articulation (the lines of greatest tension) (Fig. 163). The nearer the bone-spicules are to the medullary cavity the stronger they are (Hurtado).

In the flat and the irregular bones, the cancellous tissue is between the layers of compact bone, and is called the diploe.

A Short Bone is composed chiefly of cancellous tissue, which is encased in a thin coat of compact substance (substantia corticalis).

A Long Bone consists of a shaft, or diaphysis, and two extremities, or epiphyses. The shaft is an osseous tube, the outer layer of which is compact, and the inner layer of which is cancellous. It surrounds the medullary cavity (caevum medullare), which, in the recent condition, contains the medulla, or marrow (medulla ossium), which substance enters into the nearest Haversian canals. This cavity is widest at the centre of the shaft, and narrows toward the ends, where it is encroached upon by the cancellous layer which lies within the compact layer.

There are two varieties of marrow: Yellow marrow (medulla ossium flava) is found in the medullary cavities of the shafts of the long bones. It is composed of a network of fibrous tissue carrying many blood-vessels, fat-cells, and a few large nucleated masses of protoplasm—the true marrow-cells, or myelocytes. The yellow color of the marrow is due to fat. Yellow marrow is derived from red marrow by an increase in fat and diminution in marrow elements; it plays no part in blood-formation. At the periphery of the marrow cavity the fibrous tissue of the network forms a firm, fibrous membrane lining the cavity. This represents an inner periosteum, and is called the endostea.

Red marrow (medulla ossium rubra) is found in the diploe of the cranial bones, in the cancellous tissue of the vertebrae, ribs, and sternum, and in the articular ends of the long bones. Red marrow contains much less fat and is less solid than yellow marrow. It consists of a delicate network of connective tissue, supporting a dense capillary plexus; some fat; and numerous cellular elements. The delicate fibrous membrane surrounding red marrow is called the endostea. The cellular elements of red marrow (Fig. 2) comprise, first, marrow-cells, or myelocytes, which are protoplasmic masses, capable of ameboid movements, and containing large nuclei. They are not found in normal blood, but are abundant in leukaemia; second, small, nucleated, reddish cells called erythroblasts, resembling the nucleated red cells of the blood of the embryo, and eventually by the loss of their nuclei becoming red blood-corpuscles; third, non-nucleated red blood-corpuscles; fourth, giant-cells containing one or more nuclei. They are varieties of leuкоocytes. The leukocyte group also contains the osteoclasts, eosinophiles, and mast-cells.

Gelatinous or mucoid marrow is formed by the absorption of the fat and the cellular elements of yellow marrow, and by the serous infiltration of the intercellular substance. It is produced by starvation, old age, and certain pathological conditions.

Each extremity of a long bone is separated from the shaft by a layer of cartilage known as the cambium layer, the epiphysial cartilage, or the epiphysial disk (Fig. 8). Growth from the cartilages causes an increase in the length of the bone. The cartilages ossify during development, and effect a bony union
between the shaft and the head of the bone. Certain bony processes are separated from the bone by cartilage, which later ossifies.

A Flat Bone is composed of two layers of compact bone with a layer of cancellous bone (the diploe) interposed. There is no general marrow-cavity; but the spaces between the bone-spicules intercommunicate and contain marrow.

The Periosteum is a fibrous membrane adhering to the surface of the bone in nearly every part except at the cartilage-covered extremities. When strong tendons or ligaments are attached to the bone, the periosteum is incorporated with them. By means of the periosteum many vessels reach and enter the hard bone through Volkmann's canals. This is shown by stripping the periosteum from the surface of living bone, when small bleeding points are seen, each of which marks the entrance of a vessel from the periosteum. It thus becomes obvious that the loosening of the periosteum, by depriving a portion of the bone of its nourishment, may produce necrosis. The membrane is firmly attached to the bone by trabeculae of fibrous tissue, which penetrate the bone at right angles to its surface, and carry blood-vessels. These trabeculae are called the fibres of Sharpey (Fig. 3). They do not directly enter the Haversian systems, but only the circumferential and intermediate lamellæ—parts that are formed by periosteal action. Prolongations from some of these vessels reach the Haversian canals, and even the bone-marrow. In the extremities of a long bone, vessels from the periosteum penetrate the layer of compact bone and reach the cancellous tissue. In the newborn and in the young the periosteum is composed of three layers: an outer or fibrous layer, containing some blood-vessels, and composed of bundles of white fibrous tissue; a middle or fibro-elastic layer, containing some blood-vessels, fibrous tissue, and much elastic tissue; and an inner or osteogenetic layer, which is very vascular and contains numerous cells, which are converted into osteoblasts. These are the cells that form osseous tissue.
Transverse Section of Compact Bone (Figs. 1, 4, and 6).—As previously stated, dense bone differs from cancellous bone in the fact that the bone-plates of the former are arranged in Haversian systems, so named from the anatomist Havers. A Haversian system consists of a central canal, running in a more or less longitudinal or slightly curved or spiral direction and called the Haversian canal; from five to ten bone-plates, or lamellæ, arranged concentrically around the canal; gaps, called lacunae, between the lamellæ, which spaces contain bone-corpuscles; minute channels, or canaliculi, radiating from the lacuna and passing through the lamellæ—some reaching other lacunæ, some reaching the Haversian canal, and others passing to adjacent Haversian systems. The canaliculi contain processes from the bone-corpuscle. From a study of transverse sections it would be thought that the lamellæ always run longitudinally in straight lines or in curves determined by pressure and tension; but Prof. Dixon proved that in the human femur many of the bone-plates are arranged spirally, and thus increased strength is obtained. The same is probably true of other bones.

![Diagram of transverse section of compact tissue of bone](image)

There are four varieties of lamellæ: (1) the periosteal, peripheral, superficial, or external; (2) the Haversian, or concentric; (3) the interstitial, ground, or intermediate; and (4) the perimedullary, or internal. The periosteal lamellæ are sometimes called primary, as they are the first to appear, and are formed by the direct transformation of the inner layer of the periosteum into bone. In the shaft of a long bone there are several layers of periosteal lamellæ, but no one layer is extensive enough to surround the bone completely.

In the outer surface of the layer of periosteal lamellæ depressions exist that are known as Howship's foveolæ, or lacunæ. These depressions are made by large cells, called osteoclasts, which destroy bone. There are no Haversian canals in this outer layer, but there are some large channels that convey blood-vessels into the bone, and are known as Volkmann's canals. Many small arteries from the periosteum enter the periphery of the shaft, and also of the epiphyses. A large trunk enters the shaft by the nutrient foramen (foramen nutritius), pass along the nutrient canal (canalis nutritius), and reaches the medullary canal. This vessel is called the nutrient artery.

The Haversian or concentric lamellæ are circular layers arranged around a central space, or canal, known as the Haversian canal. There is no fixed number of these layers, there being usually from five to ten. The layers of each system are parallel to one another, but the layers of different systems cross at various
angles. Between these layers are small, irregular spaces, called lacunae; and extending radially out from the lacuna and piercing the various lamellae are delicate canals, known as canaliculi, which connect the lacunae. The lacuna nearest to the Haversian canal communicates with it by means of canaliculi; and canaliculi also communicate with other Haversian systems. The Haversian canal contains blood-vessels—an artery or a vein, or both an artery and a vein—and a nerve. The vessel in the canal is covered with endothelial cells, and the canal itself is lined with them. The space thus formed is a lymph-space, and into these lymph-spaces the canaliculi empty. Beneath the periosteum and at the periphery of the medullary cavity there are lymph-spaces that are in direct communication with the canaliculi of the Haversian systems. In each lacuna is a bone-cell—a corpuscle that almost fills the space, and sends arms, or processes, out into the canaliculi (Fig. 5). This bone-cell is an osteoblast.

The interstitial or intermediate lamellae occupy the spaces between the Haversian systems. They represent the remains of peripheral lamellae. They are usually short and very irregular, but possess lacunæ and canaliculi, which are arranged as in the Haversian systems. The perimedullary lamellæ are irregular and few in number.

The osteoblasts are irregular, flattened, stellate masses of protoplasm, possessing a number of processes. The protoplasm is granular, and each cell contains a large and distinct nucleus. Osteoblasts are met with in the deeper layer of the periosteum, in the endosteum, and in the lacunæ.

**Longitudinal Section of Compact Bone** (Figs. 6 and 7).—We do not see concentric rings, as in a transverse section, but rows of lacunæ parallel to the course of the Haversian canals—and these canals appear like half-tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance. In other respects the structure closely resembles that of a transverse section.

**Lamellæ of Cancellous Bone.**—There are no Haversian canals, and canaliculi open into the medullary spaces, which act as do the Haversian canals in compact bone.

**Blood-vessels of Bone.**—Small arteries derived from the periosteum enter the minute orifices of the compact bone (Volkmann's canals) and reach the
Haversian canals of the bony substance. Prolongations from these vessels reach the marrow and communicate with branches from the nutrient artery. The cancellous tissue is supplied by fewer but larger vessels, which are derived from the periosteum, and which often penetrate the cortex of compact bone and ramify in the cavities of the spongy tissue.

The medullary canal of a long bone is supplied by a large artery (sometimes more than one) called the **nutrient artery**. It enters the bone by the nutrient foramen, which is usually near the centre of the shaft, runs in an oblique canal through the compact structure, giving off branches to this structure, and enters the medullary cavity, and sends branches upward and downward. These branches communicate with branches from the periosteal vessels and subdivide into capillaries, which pass into comparatively large vessels. The walls of the vessels are very thin, and in some places deficient; the venous blood enters the spaces of the red marrow, and the current becomes extremely slow. Small veins collect the venous blood and emerge from the bone.

In the humerus the nutrient canal is directed toward the elbow-joint; in the radius and the ulna the nutrient canals are directed toward the elbow-joint; in the femur, the canal is directed toward the hip-joint; and in the tibia and the fibula, the canals are directed toward the ankle-joint. As Professor Cunningham states it: "In the upper limb the vessels flow toward the elbow; while in the

---

**Fig. 7.**—From a ground longitudinal section through the diaphysis of the human ulna. All canals are filled with pigment, which is here black. Haversian canals are cut longitudinally. × 90. (Saymonowicz.)
lower limb they pass from the knee.” The red marrow of the extremities and the medulla of the entire shaft, and the bone of the shaft, except the circumferential lamellae, are supplied by the nutrient artery. The circumferential lamellae, wholly, and the cancellous tissue of the extremities, in part, and the medulla of the shaft to a very small extent are supplied by vessels from the periosteum. The extremities of a bone also receive articular arteries. In most of the flat bones, and in some of the short bones, one or more large apertures exist for the passage of blood-vessels to the central parts of the bone.

Veins emerge from the long bones in three places: 1. One or two large veins accompany the nutrient artery. 2. Numerous veins emerge at the articular extremities. 3. Many small veins arise in and emerge from compact substance. The latter two classes do not accompany arteries. The veins in the marrow and in the bone are devoid of valves; but immediately after emerging from the bone they have numerous valves.

In the flat cranial bones the veins are numerous and large; as seen in diploic canals, the walls of which are composed of osseous tissue, perforated, here and there, for branches from adjacent canelli. In all cancellous tissue the venous channels are similarly arranged, and the veins have very thin coats and are without valves. When the bone is divided, the vessels remain open; they do not retract into their bony canals, and readily absorb any septic matter that may be present.

The lymphatics are chiefly periosteal; but some enter the bone, along with the vessels. Cruikshank has traced them into the substance of the bone and Klein has described them as running in the Haversian canals. The perivascular spaces of the Haversian canals are lymph-spaces.

Nerves are partly medullated and partly non-medullated, are distributed freely to the periosteum, and some of the fibres terminate in this structure as Pacinian corpuscles. Nerves accompany the nutrient arteries into the interior of the bone, and also reach the marrow from the periosteum by way of Volkmann’s canals and the Haversian canals. They certainly supply the arterial coats. It is not, as yet, determined whether nerves do or do not terminate in bone-tissue. Ströh maintains that occasionally they terminate in bone-corpuscles. According to Kölliker nerves are most numerous in the articular extremities of the long bones, in the vertebrae, and the large flat bones.

Chemical Composition of Bone.—Bone consists of an animal and an earthy part intimately combined.

The animal part may be obtained by immersing the bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied into a knot. If now a transverse section is made, the same general arrangement of the Haversian canals, lamellae, lacune, and canaliculi is seen, though not so plainly, as in the ordinary section.

The earthy part may be obtained separate by calcination, by which the animal matter is completely burned out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble with the slightest force. The earthy matter confers on bone its hardness and rigidity, and the animal matter its tenacity.

The mineral matter consists of phosphate, carbonate, and fluoride of calcium, chloride of sodium, and phosphate of magnesium.

The animal basis is largely composed of ossein, or fat collagen. When boiled with water, especially under pressure, fat collagen is almost entirely resolved into gelatin.

The organic matter of bone forms about one-third; the inorganic matter, two-thirds. The exact composition, according to Professor Cunningham, is, of
organic matter, 31.04 parts; of inorganic matter, 68.97 parts. Of the earthy matter, five-sixths is calcium phosphate. Even after the removal of all the marrow a small percentage of fat is still found in bone.

Some of the diseases to which bones are liable mainly depend on the disproportion between the two constituents of bone. Thus in the disease called rickets, so common in the children of the poor, the bones become bent and curved, either from the superincumbent weight of the body or under the action of certain muscles. This depends upon some defect of nutrition by which bone becomes deprived of its normal proportion of earthy matter, while the animal matter is of unhealthy quality. In the vertebrae of a rickety subject Bostock found in 100 parts 79.75 animal and 20.25 earthy matter. Osteomalacia is a disease of adults characterized by the decalcification of existing bone and by the failure in calcification of new osteoid material. In this disease the bone shows a diminution in inorganic and an increase in organic material. Senile atrophy renders bones porous and brittle, and portions of bone may actually be absorbed, as is seen in the disappearance of the alveoles in old age. In senile atrophy of the calvaria the outer table becomes very thin, porous, and brittle, and the inner table often becomes rough and thicker from the formation of new bone. In senile atrophy of a long bone there is absorption of bone from the surface by osteoclasts in Howship's lacunae, and absorption of the inner surface. The bone becomes porous and the medulla becomes more fatty. This change is not, as was so long taught, a decrease in organic matter and an increase in mineral matter, but is an actual alteration in the structure of the bone.

Ossification and Growth of Bone.—For the early development of the skeleton the reader is referred to text-books on embryology. Embryonic connective-tissue cells of the mesoblast develop membrane. Membrane may become bone directly or cartilage may be deposited, which cartilage by the process of ossification is formed into bone. The tissue which is eventually to become bone contains cellular elements which evolve into osteoblasts, or bone-forming cells. Osteoblasts exist in the connective tissues which become bone by intramembranous ossification, and in the deeper layers of the tissue called perichondrium which invests cartilage and which becomes the osteogenetic layer of the periosteum. In view of the fact that in the fetal skeleton some bones are preceded by membrane (parietal bones, frontal bone, upper part of tabular surface of occipital bone, most of bones of the face), and others are preceded by rods of cartilage (the long bones), two kinds of ossification are described—viz., the intramembranous and the intracartilaginous. Professor Cunningham says all true bone may be correctly regarded as of membranous origin, though its appearance is preceded in some instances by the deposition of cartilage; in this case calcification of the cartilage is an essential stage in the process of bone formation, but the ultimate conversion into true bone, with characteristic Haversian systems, leads to the absorption and disappearance of this primitive calcified cartilage. Intramembranous ossification forms membrane bones, that is, forms bone directly from fibrous tissue, there being no intermediate cartilaginous stage.

Intracartilaginous ossification consists in the ossification of cartilage.

![Schematic diagram, showing epiphysis and diaphysis and line of ossification. Ep. Epiphysis of endochondral bone. zpt. Zone of proliferation. za. Zone of calcification. ca. Cartilage. (Poirier and Charpy.)](image-url)
Intramembranous Ossification.—In the case of bones which are developed in membrane no cartilaginous mould precedes the appearance of the bone-tissue. The membrane, which occupies the place of the future bone, is of the nature of connective tissue, and ultimately forms the periosteum. At this stage it is seen to be composed of fibres and granular cells in a matrix. The outer portion is more fibrous, while internally the cells or osteoblasts predominate; the whole tissue is richly supplied with blood-vessels. At the outset of the process of bone-formation a little network of bony spicules is first noticed radiating from the point or centre of ossification. When these rays of growing bone are examined with a microscope, they are found to consist at their growing point of a network of fine, clear fibres and granular corpuscles, with an intervening ground substance (Fig. 9). The fibres are termed osteogenetic fibres, and are made up of fine fibrils differing little from those of white fibrous tissue. Like them, they are probably deposited in the matrix through the influence of the cells—in this case the osteoblasts. The osteogenetic fibres soon assume a dark and granular appearance from the deposition of calcareous granules in the fibres and in the intervening matrix, and as they calcify they are found to enclose some of the granular corpuscles or osteoblasts. By the fusion of the calcareous granules the bony tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunae. As the osteogenetic fibres grow out to the periphery they continue to calcify, and give rise to fresh bone-spicules. Thus a network of bone is formed, the meshes of which contain the blood-vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculae thicken by the addition of fresh layers of bone formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently successive layers of bony tissue are deposited under the periosteum and around the larger vascular channels, which become the Haversian canals, so that the bone increases much in thickness.

Intracartilaginous Ossification.—Just before ossification begins the bone is entirely cartilaginous, and in the long bone, which may be taken as an example, the process commences in the centre and proceeds toward the extremities, which for some time remain cartilaginous. Subsequently a similar process commences in one
or more places in those extremities and gradually extends through them. The extremities do not, however, become joined to the shaft by bony tissue until growth has ceased, but are attached to it by a layer of cartilaginous tissue termed the **epiphyseal cartilage** (Fig. 8).

The first step in the ossification of the cartilage is that the cartilage-cells, at the point where ossification is commencing and which is termed a **centre of ossification**, enlarge and arrange themselves in rows (Fig. 10). The matrix in which they are embedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in this matrix, between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and transverse bars of calcified substance stretch across from one calcareous column to another. Thus there are longitudinal groups of the cartilage-cells enclosed in oblong cavities, the walls of which are formed of calcified matrix, which cuts off all nutrition from the cells, and they, in consequence, waste, leaving spaces called the **primary areolae** (Sharpey).

At the same time that this process is going on in the centre of the solid bar of cartilage of which the foetal bone consists, certain changes are taking place on
its surface. This is covered by a very vascular membrane, the *perichondrium*, entirely similar to the embryonic connective tissue already described as constituting the basis of membrane-bone, on the inner surface of which, that is to say, on the surface in contact with the cartilage, are gathered the formative cells, the *osteoblasts*. By the agency of these cells a thin layer of bony tissue is being formed between the perichondrium and the cartilage, by the *intramembranous* mode of ossification just described. There are, then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, formed of calcified matrix and containing the withered cartilage-cells, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium, which has now become periosteum (Fig. 10, *ir*). The processes consist of blood-vessels and cells—*osteoblasts*, or *bone-formers*, and *osteoclasts*, or *bone-destroyers*. The latter are similar to the giant-cells (myelo-plaques) found in marrow, and they excavate passages through

![Fig. 12.—Transverse section from the femur of a human embryo about eleven weeks old. a. A medullary sinus cut transversely, and b, another, longitudinally. c. Osteoblasts. d. the new-formed bony layer by absorption, and pass through it into the calcified matrix (Fig. 10). Wherever these processes come in contact with the calcified walls of the primary areole they absorb it, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areole* (Sharpey), or *medullary spaces* (Müller). In these secondary spaces the original cartilage-cells, having disappeared, become filled with embryonic marrow, consisting of osteoblasts and vessels, and derived in
the manner described above, from the osteogenetic layer of the periosteum (Fig. 11).

Thus far there has been traced the formation of enlarged spaces (secondary areolae), the perforated walls of which are still formed by calcified cartilage-matrix, containing an embryonic marrow, derived from the processes sent in from the osteogenetic layer of the periosteum, and consisting of blood-vessels and round-cells, osteoblasts (Fig. 11). The walls of these secondary areolae are at this time of only inconsiderable thickness, but they become thickened by the deposition of layers of new bone on their interior. This process takes place in the following manner: Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as an epithelioid layer on the surface of the wall of the space (Fig. 12). This layer of osteoblasts form a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance. On this a second layer of osteoblasts arrange themselves, and in their turn form an osseous layer. By the repetition of this process the original cavity becomes very much reduced in size, and at last only remains as a small circular hole in the centre, containing the remains of the embryonic marrow—that is, a blood-vessel and a few osteoblasts. This small cavity constitutes the Haversian canal of the perfectly ossified bone. The successive layers of osseous matter which have been laid down and which encircle this central canal constitute the lamellae of which, as we have seen, each Haversian system is made up. As the successive layers of osteoblasts form osseous tissue, certain of the osteoblastic cells remain included between the various bony layers. These persist as the corpuscles of the future bone, the spaces enclosing them forming the lacunae (Figs. 12 and 14). The canaliculi, at first extremely short, are supposed to be extended by absorption, so as to meet those of neighboring lacunae.

Such are the changes which may be observed at one particular point, the centre of ossification. While they have been going on here a similar process has been set up in the surrounding parts and has been gradually proceeding toward the end of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

Thus far, then, we have followed the steps of a process by which a solid bony mass is produced, having vessels running into it from the periosteum, Haversian canals in which those vessels run, medullary spaces filled with foetal marrow, lacunae with their contained bone-cells, and canaliculi growing out of these lacunae.

This process of ossification, however, is not the origin of the whole of the skeleton, for even in those bones in which the ossification proceeds in a great measure from a single centre, situated in the cartilaginous shaft of a long bone, a considerable part of the original bone is formed by intramembranous ossification.
beneath the perichondrium or periosteum; so that the girth of the bone is increased by bony deposit from the deeper layer of this membrane. The shaft of the bone is at first solid, but a tube is hollowed out in it by absorption around the vessels passing into it, which becomes the medullary canal. This absorption is supposed to be brought about by large "giant-cells," the so-called osteoclasts of Kölliker (Fig. 11). They vary in shape and size, and are known by containing a large number of clear nuclei, sometimes as many as twenty. The occurrence of similar cells in some tumors of bones has led to such tumors being denominated "myeloid."

As more and more bone is removed by this process of absorption from the interior of the bone to form the medullary canal, so more and more bone is deposited on the exterior from the periosteum, until at length the bone has attained the shape and size which it is destined to retain during adult life. As the ossification of the cartilaginous shaft extends toward the articular ends it carries with it, as it were, a layer of cartilage, or the cartilage grows as it ossifies, and thus the bone is increased in length. During this period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous; then a bony centre appears in it, and it commences the same process of intracartilaginous ossification; but this process never extends to any great distance. The epiphyses remain separated from the shaft by a narrow cartilaginous layer for a definite time (Fig. 8). This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to the processes of bone which are separately ossified, such as the trochanters of the femur. The bones, having been formed, continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place within, by which the medullary cavity is increased.

The medullary spaces which characterize the cancellous tissue are produced by the absorption of the original foetal bone in the same way as the original medullary canal is formed. The distinction between the cancellous and compact tissue appears to depend essentially upon the extent to which this process of absorption has been carried; and we may perhaps remind the reader that in morbid states of the bone inflammatory absorption produces exactly the same change, and converts portions of bone naturally compact into cancellous tissue.

The number of ossific centres is different in different bones. In most of the short bones ossification commences by a single point in the centre, and proceeds toward the circumference. In the long bones there is a central point of ossification for the shaft or diaphysis; and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The union of the epiphyses with the shaft takes place in the reverse order to that in which their ossification began, with the exception of the fibula, and appears to be regulated by direction of the nutrient artery of the bone. Thus the nutrient arteries of the bones of the arm and forearm are directed toward the elbow, and the epiphyses of the bones forming this joint become united to the shaft before those at the shoulder and wrist. In the lower limb, on the other hand, the nutrient arteries pass in a direction from the knee; that is, upward in the femur, downward in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur and the lower epiphysis of the tibia and fibula become first united to the shaft.

Where there is only one epiphysis, the medullary artery is directed toward that end of the bone where there is no additional centre, as toward the acromial end of the clavicle, toward the distal end of the metacarpal bone of the thumb
and great toe, and toward the proximal end of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For an account of these the reader is referred to the description of the individual bones in the sequel.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that on the application of severe force to a joint the epiphysis becomes separated from the shaft, and such an injury may be mistaken for a fracture or dislocation.

**THE VERTEBRAL OR SPINAL COLUMN (THE SPINE) (COLUMNA VERTEBRALIS).**

The spine is a flexuous and flexible column formed of a series of bones called *vertebrae* (from *vertere*, to turn).

The vertebrae are thirty-three in number, and have received the names *cervical*, *dorsal* or *thoracic*, *lumbar*, *sacral*, and *coccygeal*, according to the position which they occupy; seven being found in the cervical region, twelve in the dorsal, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or the number may be diminished in one region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the spine, the number of bones forming which is seldom increased or diminished.

The vertebrae in the upper three regions of the spine remain separate throughout life, and are known as *true* or *movable* vertebrae; but those found in the sacral and coccygeal regions are in the adult firmly united, so as to form two bones—five entering into the formation of the upper bone or *sacrum*, and four into the terminal bone of the spine or *coccyx*. The fused vertebrae are known as *false* or *immovable* vertebrae.

**GENERAL CHARACTERS OF A VERTEBRA.**

Each vertebra consists of two essential parts—an anterior solid segment, the *body*, or *centrum*, and a posterior segment, the *arch* (arcus vertebræ), or the *neural arch*. The neural arch is formed of *two pedicles* and *two laminae*, supporting *seven processes*—viz., *four articular*, two *transverse*, and one *spinous*.

The bodies of the vertebrae are piled one upon the other, forming a strong pillar for the support of the cranium and trunk; the arches forming a hollow cylinder behind the bodies for the protection of the spinal cord (spinal canal or *neural canal*). The different vertebrae are connected together by means of the articular processes and the intervertebral fibrocartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the spine. Lastly, between each pair of vertebrae apertures exist through which the spinal nerves pass from the cord. Each of these constituent parts must now be separately examined.

**Body, or Centrum (corpus vertebrae).**—The body is the largest part of a vertebra. Above and below it is flattened; its upper and lower surfaces are rough for the attachment of the intervertebral fibro-cartilages, and each presents a rim around its circumference. In front it is convex from side to side, concave from above downward. Behind it is flat from above downward and slightly concave from
side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; while on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins from the body of the vertebra—the **vena basis vertebræ**.

**Pedicles.**—The pedicles are two short, thick pieces of bone, which project backward, one on each side, from the upper part of the body of the vertebra, at the line of junction of its posterior and lateral surfaces. Each pedicle (**radix arcus vertebræ**) is a root of the vertebral arch. The concavities above and below the pedicles are the **superior and inferior intervertebral notches** or **grooves** (**incisura vertebralis superior et inferior**); they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebrae are articulated the notches of each contiguous pair of bones form the **intervertebral foramina** (**foramina intervertebralia**), which communicate with the spinal canal and transmit the spinal nerves and bloodvessels.

**Laminae.**—The laminae are two broad plates of bone which complete the neural arch by fusing together in the middle line behind. They enclose a foramen, the **spinal** or **vertebral foramen** (**foramen vertebrale**), which serves for the protection of the spinal cord. When the vertebrae are joined they form, with their ligaments, the **vertebral canal** (**spinal or neural canal, canalis vertebralis**). The laminae are connected to the body by means of the pedicles. Their upper and lower borders are rough, for the attachment of the ligamenta subflava.

**Processes.** **Spinous Process** (**processus spinosus**).—The spinous process projects backward from the junction of the two laminae, and serves for the attachment of muscles and ligaments.

**Articular Processes.**—The articular processes (**zygapophyses**), four in number, two on each side, spring from the junction of the pedicles with the laminae. Each **superior process** (**processus articularis superior**) projects upward, its **articular surface** (**facies articularis superior**) being directed more or less backward; each **inferior process** (**processus articularis inferior**) projects downward, its **articular surface** (**facies articularis inferior**) looking more or less forward.\(^1\)

**Transverse Processes** (**processus transversi**).—The transverse processes, two in number, project one at each side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They also serve for the attachment of muscles and ligaments.

---

**The Cervical Vertebrae** (**Vertebrae Cervicales**) (Fig. 15).

The cervical vertebrae are smaller than those in any other region of the spine, and may be readily distinguished by the foramen in the transverse process, which does not exist in the transverse process of either a dorsal or lumbar vertebra.

**Body.**—The body (**centrum**) is small, comparatively dense, and broader from side to side than from before backward. The **anterior and posterior surfaces** are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downward, so as to overlap the upper and fore part of the vertebra below. Its **upper surface** is concave transversely, and presents a projecting lip on each side; its **lower surface** is convex from side to side, concave from before backward, and presents laterally a shallow concavity which receives the corresponding projecting lip of the adjacent vertebra.

**Pedicles.**—The pedicles are directed outward and backward, and are attached to the body midway between the upper and lower borders, so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower.

---

\(^1\) It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.
Laminae.—The laminae are narrow, long, thinner above than below, and overlap each other, enclosing the spinal foramen, which is very large, and of a triangular form.

Processes. Spinous Process.—The spinous process is short, and bifid at the extremity, to afford greater extent of surface for the attachment of muscles, the two divisions being often of unequal size. They increase in length from the fourth to the seventh vertebra.

Articular Processes.—The articular processes are flat, oblique, and of an oval form; the superior are directed backward and upward; the inferior forward and downward.

Transverse Processes.—The transverse processes are short, directed downward, outward, and forward, bifid at their extremity, and marked by a groove along their upper surface, which runs downward and outward from the superior intervertebral notch and serves for the transmission of one of the cervical nerves. They are situated in front of the articular processes and on the outer side of the pedicles. The transverse processes are pierced at their base by a foramen, for the transmission of the vertebral artery, vein, and a plexus of sympathetic nerves. This foramen is known as the transverse foramen, the costotransverse foramen, and the vertebrarterial foramen (foramen transfversarium). Each process is formed by two roots: the anterior root, sometimes called the costal process, arising from the side of the body, and is the homologue of the rib in the dorsal region of the spine; the posterior root springs from the junction of the pedicle with the lamina, and corresponds with the transverse process in the dorsal region. It is by the junction of the two that the foramen for the vertebral vessels is formed. The extremity of each of the anterior roots forms the anterior tubercle (tuberculum anterius) and the extremity of each of the posterior roots the posterior tubercle (tuberculum posterius) of the transverse processes.¹

The peculiar vertebra in the cervical regions are the first, or atlas; the second, or axis; and the seventh, or vertebra prominens. The great modifications in the form of the atlas and axis are designed to admit of the nodding and rotatory movements of the head.

Atlas.—The atlas (Fig. 16) is so named from supporting the globe of the head. The chief peculiarities of this bone are that it has neither body nor spinous process. The body is detached from the rest of the bone, and forms the odontoid process of

¹ The anterior tubercle of the transverse process of the sixth cervical vertebra is of large size, and is sometimes known as "Chassaignac's" or the "carotid tubercle" (tuberculum carotideum). It is in close relation with the carotid artery, which lies in front and a little external to it; so that, as was first pointed out by Chassaignac, the vessel can with ease be compressed against it.
the second vertebra; while the parts corresponding to the pedicles join in front to form the anterior arch. The atlas is ring-like, and consists of an anterior arch, a posterior arch, and two lateral masses. The anterior arch (arcus anterior) forms about one-fifth of the ring; its anterior surface is convex, and presents about its centre a tubercle (tuberculum anterius), for the attachment of the Longus colli muscle; posteriorly it is concave, and marked by a smooth, oval facet, called the circular facet (fovea dentis), covered with cartilage, for articulation with the odontoid process of the axis. The upper and lower borders give attachment to the anterior occipito-atlantal and the anterior atlanto-axial ligaments, which connect it with the occipital bone above and the axis below. The posterior arch (arcus posterior) forms about two-fifths of the circumference of the bone; it terminates behind in a tubercle (tuberculum posterus), which is the rudiment of a spinous process, and gives origin to the Rectus capitis posticus minor. The diminutive size of this process prevents any interference in the movements between the atlas and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipito-atlantal ligament, while in front, immediately behind each superior articular process, is a groove (sulcus articularis vertebralis), sometimes converted into a foramen by a delicate bony spiculum, which arches backward from the posterior extremity of the superior articular process. These grooves represent the superior intervertebral notches, and are peculiar from being situated behind the articular processes, instead of in front of them, as in the other vertebrae. They serve for the transmission of the vertebral artery, which, ascending through the foramen in the transverse process, winds round the lateral mass in a direction backward and inward. They also transmit the suboccipital (first spinal) nerve. On the under surface of the posterior arch, in the same situation, are two other grooves, placed behind the lateral masses, and representing the inferior intervertebral notches of other vertebrae. They are much less marked than the superior. The lower border also gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The lateral masses (massae laterales) are the most bulky and solid parts of the atlas, in order to support the weight of the head; they present two articulating surfaces above, and two below. Each superior process (fovea articularis superior) is of large size, oval, concave, and approaches its companion in front, but diverges from it behind; it is directed upward, inward, and a little backward, forming a kind of cup for the corresponding condyle of the occipital bone. The two processes are admirably adapted to the nodding movements of the head. Not infrequently they are partially subdivided by a more or less deep indentation, which encroaches upon each lateral margin. Each inferior articular process (facies articularis inferior)
is circular in form, flattened or slightly concave, and directed downward and inward, articulating with the axis. The inferior processes permit the rotatory movements. Just below the inner margin of each superior articular surface is a small tubercle, for the attachment of the transverse ligament, which, stretching across the ring of the atlas, divides it into two unequal parts or arches; the anterior or smaller segment receiving the odontoid process of the axis, the posterior allowing the transmission of the spinal cord and its membranes. This part of the spinal canal is of considerable size, to afford space for the spinal cord; and hence lateral displacement of the atlas may occur without compression of this structure. The transverse processes are of large size, project directly outward and downward from the lateral masses, and serve for the attachment of special muscles which assist in rotating the head. They are long, not bifid, and perforated at their base by a canal for the vertebral artery, which is directed from below, upward, and backward.

**Axis.**—The axis (epistropheus) (Fig. 17) is the pivot upon which the first vertebra, carrying the head, rotates, hence the name, axis. The most distinctive character of this bone is the strong, prominent process, tooth-like in form (hence the name odontoid process, or dens), which rises perpendicularly from the upper surface of the body. The body is deeper in front than behind, and prolonged downward anteriorly so as to overlap the upper and fore part of the next vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions, for the attachment of the Longus colli muscle of either side. The odontoid process presents two articulating surfaces covered with cartilage: one in front, of an oval form, for articulation with the atlas (facies articularis anterior); another behind (facies articularis posterior), for the transverse ligament—the latter frequently encroaching on the sides of the process. The apex is pointed, and gives attachment to the middle odontoid ligament (ligamentum apicis dentis). Below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the lateral fasciculi of the odontoid or check ligaments, which connect it to the occipital bone; the base of the process, where it is attached to the body, is constricted, so as to prevent displacement from the transverse ligament, which binds it in this situation to the anterior arch of the atlas. Sometimes, however, this process does become displaced, especially in children, in whom the ligaments are more relaxed: instant death is the result of this accident. The internal structure of the odontoid process is more compact than that of the body. The pedicles are broad and strong, especially their anterior extremities, which coalesce with the sides of the body and the
root of the odontoid process. The laminae are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The transverse processes are very small, not bifid, and each is perforated by the foramen for the vertebral artery, which is directed obliquely upward and outward. The superior articular surfaces (facies articulares superiores) are round, slightly convex, directed upward and outward, and are peculiar in being supported on the body, pedicles, and transverse processes. The inferior articular surfaces (facies articulares inferiores) have the same direction as those of the other cervical vertebrae. The superior intervertebral notches are very shallow, and lie behind the articular processes; the inferior in front of them, as in the other cervical vertebrae. The spinous process is of large size, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity for the attachment of muscles which serve to rotate the head upon the spine.

Seventh Cervical (Fig. 18).—The most distinctive character of this vertebra is the existence of a very long and prominent spinous process; hence the name vertebra prominens. This process is thick, nearly horizontal in direction, not bifurcated, and has attached to it the lower end of the ligamentum nuchae. The transverse process is usually of large size, its posterior tubercles are large and prominent, while the anterior are small and faintly marked; its upper surface has usually a hollow groove, and it seldom presents more than a trace of bifurcation at its extremity. The foramen in the transverse process is sometimes as large as in the other cervical vertebrae, but is usually smaller on one or both sides, and is sometimes wanting. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen. Occasionally the anterior root of the transverse process exists as a separate bone, and attains a large size. It is then known as a cervical rib.

The Thoracic or Dorsal Vertebrae (Vertebrae Thoracales).

The dorsal vertebrae are intermediate in size between those in the cervical and those in the lumbar region, and increase in size from above downward, the upper vertebra in this segment of the spine being much smaller than those in the lower part of the region. The dorsal vertebrae may be at once recognized by the presence on the sides of the body of one or more facets or half-facets for the heads of the ribs. Bodies.—The bodies of the dorsal vertebrae resemble those in the cervical and lumbar regions at the respective ends of this portion of the spine; but in the middle of the dorsal region their form is very characteristic, being heart-shaped, and as broad in the anteroposterior as in the lateral direction. They are thicker behind than in front, flat above and below, convex and prominent in front, deeply con-
eave behind, slightly constricted in front and at the sides, and marked on each side, near the root of the pedicle, by two demi-facets, one above, the other below (fovea costalis superior et inferior). These are covered with cartilage in the recent state, and, when articulated with the adjoining vertebra, form, with the intervening fibro-cartilage, oval surfaces for the reception of the heads of the corresponding ribs. The tenth, eleventh, and twelfth dorsal vertebrae each possesses one complete facet for the head of the rib, instead of two demi-facets.

**Pedicles.**—The pedicles are directed backward, and the inferior intervertebral notches are of large size, and deeper than in any other region of the spine.

**Laminae.**—The laminae are broad, thick, and imbricated—that is to say, overlapping one another like tiles on a roof. The spinal foramen is small, and of a circular form.

**Processes.** **Spinous Processes.**—Each spinous process is long, triangular on transverse section, directed obliquely downward, and terminates in a tubercular extremity. They overlap one another from the fifth to the eighth vertebra, but are less oblique in direction above and below.

**Articular Processes.**—The articular processes are flat, nearly vertical in direction, and project from the upper and lower part of the pedicles; the superior being directed backward and slightly outward and upward, the inferior forward and a little inward and downward.

**Transverse Processes.**—The transverse processes arise from the same parts of the arch as the posterior roots of the transverse processes in the neck, and are situated behind the articular processes and pedicles; they are thick, strong, and of great length, directed obliquely backward and outward, presenting a clubbed extremity, which is tipped on its anterior part by a small concave surface, for articulation with the tubercle of a rib (fovea costalis transversalis). The twelfth, the eleventh, and sometimes the tenth dorsal vertebra has no facet on the transverse process. Besides the articular facet for the rib, three indistinct tubercles may be seen arising from the transverse processes: one at the upper border, one at the lower border, and one externally. In man they are comparatively of small size, and serve only for the attachment of muscles. But in some animals they attain considerable magnitude, either for the purpose of more closely

![Diagram of a dorsal vertebra](image-url)
connecting the segments of this portion of the spine or for muscular and ligamentous attachment.

The peculiar dorsal vertebrae are the first, ninth, tenth, eleventh, and twelfth (Fig. 20).

**First Dorsal Vertebra.**—The first dorsal vertebra presents, on each side of the body, a single entire articular facet for the head of the first rib and a half facet for the upper half of the second. The body is like that of a cervical vertebra, being broad transversely its upper surface is concave, and lipped on each side. The articular surfaces are oblique, and the spinous process thick, long, and almost horizontal.

**Ninth Dorsal Vertebra.**—The ninth dorsal has no demi-facet below. In some subjects, however, the ninth has two demi-facets on each side; when this occurs the tenth has only a demi-facet at the upper part.
Tenth Dorsal Vertebra.—The tenth dorsal has (except in the cases just mentioned) an entire articular facet on each side, above, which is partly placed on the outer surface of the pedicle. It has no demi-facet below.

Eleventh Dorsal Vertebra.—In the eleventh dorsal the body approaches in its form and size to the lumbar. The articular facets for the heads of the ribs, one on each side, are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the dorsal region. The spinous process is short, and nearly horizontal in direction. The transverse processes are very short, tubercular at their extremities, and have no articular facets for the tubercles of the ribs.

Twelfth Dorsal Vertebra.—The twelfth dorsal has the same general characters as the eleventh, but may be distinguished from it by the inferior articular processes, being convex and turned outward, like those of the lumbar vertebrae; by the general form of the body, laminae, and spinous process, approaching to that of the lumbar vertebrae; and by the transverse processes being shorter, and marked by three elevations, the superior, inferior, and external tubercles, which correspond to the mammillary, accessory, and transverse processes of the lumbar vertebrae. Traces of similar elevations are usually to be found upon the other dorsal vertebrae (vide ut supra).

The Lumbar Vertebrae (Vertebrae Lumbales).

The lumbar vertebrae (Fig. 21) are the largest segments of the vertebral column, and can at once be distinguished by the absence of the foramen in the transverse process, the characteristic point of the cervical vertebrae, and by the absence of any articulating facet on the side of the body, the distinguishing mark of the dorsal vertebrae.

![Fig. 21.—Lumbar vertebra.](image)

Body.—The body is large, and has a greater diameter from side to side than from before backward, slightly thicker in front than behind, flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the sides, presenting prominent margins, which afford a broad basis for the support of the superincumbent weight.

Pedicles.—The pedicles are very strong, directed backward from the upper part of the bodies; consequently, the inferior intervertebral notches are of considerable depth.

Laminae.—The laminae are broad, short, and strong, and the spinal foramen triangular, larger than in the dorsal, smaller than in the cervical, region.
Processes. Spinous Processes.—The spinous processes are thick and broad, somewhat quadrilateral, horizontal in direction, thicker below than above, and terminating by a rough, uneven border.

Articular Processes.—The superior articular processes are concave, and look backward and inward; the inferior are convex, and look forward and outward; the former are separated by a much wider interval than the latter, embracing the lower articulating processes of the vertebra above.

Transverse Processes.—The transverse processes are long, slender, directed transversely outward in the upper three lumbar vertebrae, slanting a little upward in the lower two. They are situated in front of the articular processes, instead of behind them, as in the dorsal vertebrae, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the twelfth dorsal vertebra, the superior one on each side becomes connected in this region with the back part of the superior articular process, and has received the name of mammillary process (processus mammillaris); the inferior is represented by a small process pointing downward, situated at the back part of the base of the transverse process, and called the accessory process (processus accessorius): these are the true transverse processes, which are rudimental in this region of the spine. The external one is the so-called transverse process, the homologue of the rib, and hence sometimes called the costal process (processus costarius) (Fig. 22). Although in man the costal processes are comparatively small, in some animals they attain considerable size, and serve to lock the vertebrae more closely together.

Fifth Lumbar Vertebra.—The fifth lumbar vertebra is characterized by having the body much thicker in front than behind, which accords with the prominence of the sacro-vertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articulating processes; and by the greater size and thickness of its transverse processes, which spring from the body as well as from the pedicles.
Structure of the Vertebrae.—The body is composed of light, spongy, cancellous tissue, having a thin coating of compact tissue on its external surface perforated by numerous orifices, some of large size, for the passage of vessels; its interior is traversed by one or two large canals, for the reception of veins, which converge toward a single large, irregular aperture or several small apertures at the posterior part of the body of each bone. The arch and processes projecting from it have, on the contrary, an exceedingly thick covering of compact tissue (Fig. 23).

![Bony structure of a lumbar vertebra. (Poirier and Charpy.)](image)

Development.—Each vertebra is formed of four primary centres of ossification (Fig. 24), one for each lamina and its processes, and two for the body. 1 Ossification commences in the lamina about the sixth week of foetal life, in the situation where the transverse processes afterward project, the ossific granules shooting backward to the spine, forward into the pedicles, and outward into the transverse and articular processes. Ossification in the body commences in the middle of the cartilage about the eighth week by two closely approximated centres, which

speedily coalesce to form one central ossific point. According to some authors, ossification commences in the laminae only in the upper vertebrae—i. e., in the cervical and upper dorsal. The first ossific points in the lower vertebrae are those which are to form the body, the osseous centres for the lamina appearing at a subsequent period. At birth these three pieces are perfectly separate. During the first year the laminae become united behind, the union taking place first in the lumbar region and then extending upward through the dorsal and lower cervical regions. About the third year the body is joined to the arch on each side in such a manner that the body is formed from the three original centres of ossifica-

1 By many observers it is asserted that the bodies of the vertebra are developed from a single centre which speedily becomes bilobed, so as to give the appearance of two nuclei; but that there are two centres, at all events sometimes, is evidenced by the fact that the two halves of the body of the vertebra may remain distinct throughout life and be separated by a fissure through which a protrusion of the spinal membrane may take place, constituting an anterior spinous bifida.
tion, the amount contributed by the pedicles increasing in extent from below upward. Thus the bodies of the sacral vertebre are formed almost entirely from the central nuclei; the bodies of the lumbar are formed laterally and behind by the pedicles; in the dorsal region the pedicles advance as far forward as the articular depressions for the head of the ribs, forming these cavities of reception; and in the neck the lateral portions of the bodies are formed entirely by the advance of the pedicles. The line along which union takes place between the body and the neural arch is named neuro-central suture. Before puberty no other changes occur, excepting a gradual increase in the growth of these primary centres; the upper and under surfaces of the bodies and the ends of the transverse and spinous processes being tipped with cartilage, in which ossific granules are not as yet deposited. At sixteen years (Fig. 26) three secondary centres appear, one for the tip of each transverse process, and one for the extremity of the spinous process. In some of the lumbar vertebre, especially the first, second, and third, a second ossifying centre appears at the base of the spinous process. At twenty-one years (Fig. 25) a thin, circular, epiphysical plate of bone is formed in the layer of cartilage situated on the upper and under surfaces of the body, the former being the thicker of the two. All these become joined, and the bone is completely formed between the twenty-fifth and thirtieth year of life.

Exceptions to this mode of development occur in the first, second, and seventh cervical, and in the vertebre of the lumbar region.

**Atlas** (Fig. 27).—The number of centres of ossification of the atlas is very variable. It may be developed from two, three, four, or five centres. The most frequent arrangement is by three centres. Two of these are destined for the two lateral or neural masses, the ossification of which commences about the seventh week near the articular processes, and extend backward; these portions of bone are separated from one another behind, at birth, by a narrow interval filled in with cartilage. Between the third and fourth years they unite either directly or through the medium of a separate centre developed in the cartilage in the middle line. The anterior arch, at birth, is altogether cartilaginous, and in this a separate nucleus appears about the end of the first year after birth, and, extending laterally, joins the neural processes in front of the pedicles. Sometimes there are two nuclei developed in the cartilage, one on either side of the median line, which join to form a single mass. And occasionally there is no separate centre, but the anterior arch is formed by the gradual extension forward and ultimate junction of the two neural processes.

**Axis.**—The axis (Fig. 28) is developed by seven centres. The body and arch of this bone are formed in the same manner as the corresponding parts in the other vertebrae: one centre (or two, which speedily coalesce) for the lower part of the body, and one for each lamina. The centres for the laminae appear about the
seventh or eighth week, that for the body about the fourth month. The odontoid process consists originally of an extension upward of the cartilaginous mass in which the lower part of the body is formed. At about the sixth month of foetal life two osseous nuclei make their appearance in the base of this process; they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage, the base of the process being separated from the body by a cartilaginous interval, which gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age. Finally, as Humphry has demonstrated, the apex of the odontoid process has a separate nucleus, which appears in the second year and joins about the twelfth year. In addition to these there is a secondary centre for a thin epiphysial plate on the under surface of the body of the bone. J. Bland Sutton and others maintain that the odontoid process is the "dissociated body of the atlas."  

Seventh Cervical.—The anterior or costal part of the transverse process of the seventh cervical is developed from a separate osseous centre at about the sixth month of foetal life, and joins the body and posterior division of the transverse process between the fifth and sixth years. Sometimes this process continues as a separate piece, and, becoming lengthened outward, constitutes what is known as a cervical rib. This separate ossific centre for the costal process has also been found in the fourth, fifth, and sixth cervical vertebrae.

Lumbar Vertebrae.—The lumbar vertebra (Fig. 20) have two additional centres (besides those peculiar to the vertebra generally) for the mammillary tubercles, which project from the back part of the superior articular processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently unconnected with the remaining portion of the bone, thus forming a lumbar rib—a peculiarity that is rarely met with.

Progress of Ossification in the Spine Generally.—Ossification of the laminae of the vertebrae commences in the cervical region of the spine, and proceeds gradually downward. Ossification of the bodies, on the other hand, commences a little below the centre of the spinal column (about the ninth or tenth dorsal vertebra), and extends both upward and downward. Although the ossific nuclei make their first appearance in the lower dorsal vertebrae, the lumbar and first sacral vertebrae are those in which these nuclei are largest at birth.

Attachment of Muscles.—To the Atlas are attached nine pairs: the Longus colli, Rectus capitis anticus minor, Rectus lateralis, Obliquus capitis superior and inferior, Splenius colli, Levator anguli scapulae, First Intertransverse, and Rectus capitis posticus minor.

To the Axis are attached eleven pairs: the Longus colli, Levator anguli scapulae, Splenius colli, Scalenum medius, Transversalis colli, Intertransversales, Obliquus capitis inferior, Rectus capitis posticus major, Semispinalis colli, Multifidus spine, Interspinales.

To the remaining vertebrae, generally, are attached thirty-five pairs and a single muscle: anteriorly, the Rectus capitis anticus major, Longus colli, Scalenum anticus medius and posticus, Psoas magnus and parvus, Quadratus lumborum, Diaphragm, Obliquus abdominis internus, and Transversalis abdominis; posteriorly, the Trapezius, Latissimus dorsi, Levator anguli scapulae, Rhomboideus major and minor, Serratus posticus superior and inferior, Splenius, Erector spine, Ilio-costalis, Longissimus dorsi, Spinalis dorsi, Cervicalis ascendens, Transversalis colli, Trachelo-mastoid, Complexus, Biventer cervicis, Semispinalis dorsi and colli, Multifidus spine, Rotatores spine, Interspinales, Supraspinales, Intertransversales, Levatores costarum.

2 Ligaments: their Nature and Morphology.
The Sacral and Coccygeal Vertebrae (False or Immovable Vertebrae).

The sacral and coccygeal vertebrae consist, at an early period of life, of nine separate pieces, which are united in the adult so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Occasionally, the coccyx consists of five bones.\footnote{Sir George Humphry describes this as the usual composition of the coccyx. On the Skeleton, p. 456.}

Sacrum (os sacrum).—The os sacrum (sacer, sacred), the sacred bone. So called, according to some, because it was the part selected in sacrifices. Another view is that the name is derived from an opinion of the Jewish rabbis, that this part of the skeleton strongly resists decay and becomes the germ from which the new body will be raised. The sacrum is a large, triangular bone (Fig. 30), situated at the lower part of the vertebral column, and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base articulating with the last lumbar vertebra, its apex with the coccyx. It is composed of five segments of bone (sacral vertebrae, or vertebrae sacrales). The sacrum is curved upon itself, and placed very obliquely, its upper extremity projecting forward, and forming, with the last lumbar vertebra, a very prominent angle, called the promontory (promontorium), or sacro-vertebral angle; while its central part is directed backward, so as to give increased capacity to the pelvic cavity. It presents for examination an anterior and posterior surface, two lateral surfaces, a base, an apex, and a central canal.

Surfaces. Anterior or Pelvic Surface (facies pelvina).—The anterior surface is concave from above downward, and slightly so from side to side. In the middle are seen four transverse ridges (linææ transversæ), indicating the original division of the bone into five separate pieces. The portions of bone intervening
between the ridges correspond to the bodies of the vertebrae. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish in size from above downward, are flattened from before backward, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At each end of the ridges above mentioned are seen the **anterior sacral foramina** (foramina sacralia anteriora), analogous to the intervertebral foramina, four in number on each side, somewhat rounded in form, diminishing in size from above downward, and directed outward and forward; they transmit the anterior branches of the sacral nerves and the lateral sacral arteries. External to these foramina is the **lateral mass** (pars lateralis), consisting at an early period of life of separate segments; these become blended, in the adult, with the bodies, with each other, and with the posterior transverse processes. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior sacral nerves as they pass outward, the grooves being separated by prominent ridges of bone, which give attachment to the slips of the Pyriformis muscle.

If a vertical section is made through the centre of the sacrum (Fig. 31), the bodies are seen to be united at their circumference by bone, a wide interval being left centrally, which, in the recent state, is filled by intervertebral substance. In some bones this union is more complete between the lower segments than between the upper ones.

**Posterior or Dorsal Surface** (facet dor-salis).—The posterior surface (Fig. 32) is convex and much narrower than the anterior. In the middle line are three or four tubercles, which represent the rudimentary spinous processes of the sacral vertebra. Of these tubercles, the first is usually prominent, and perfectly distinct from the rest; the second and third are either separate or united into a **tubercular ridge** (crista sacralis media), which diminishes in size from above downward; the fourth usually, and the fifth always, remaining undeveloped. The gap which results from failure of the laminae to meet in the mid-line is called the **hiatus sacralis**. External to the spinous processes on each side are the **lamina**, broad and well marked in the first three pieces; sometimes the fourth, and generally the fifth, are only partially developed and fail to meet in the middle line. These partially developed laminae are prolonged downward as rounded processes, the **sacral cornua** (cornua sacralia), and are connected to the cornua of the coccyx. Between them the bony wall of the lower end of the sacral canal is imperfect. External to the laminae is a linear series of indistinct tubercles representing the **articular processes** (cristae sacrales artculaiores); the upper pair are large, well developed, and correspond in shape and direction to the superior articulating processes of a lumbar vertebra; the second and third are small; the fourth and fifth (usually blended together) are situated on each

![Fig. 31.—Vertical section of the sacrum.](image-url)
side of the sacral canal and assist in forming the sacral cornua. External to the articular processes are the four posterior sacral foramina \((\text{foramina sacralia posteri} \text{ora})\); they are smaller in size and less regular in form than the anterior, and transmit the posterior branches of the sacral nerves. On the outer side of

[Diagram of the sacrum, posterior surface]

the posterior sacral foramina is a series of tubercles, the rudimentary transverse processes of the sacral vertebra \((\text{crista sacrales laterales})\). The first pair of transverse tubercles are large, very distinct, and correspond with each superior angle of the bone; they together with the second pair, which are of small size, give attachment to the horizontal part of the sacro-iliac ligament; the third gives attachment to the oblique fasciculi of the posterior sacro-iliac ligaments; and the fourth and fifth to the great sacro-sciatic ligaments. The interspace between the spinous and transverse processes on the back of the sacrum presents a wide, shallow concavity, called the sacral groove: it is continuous above with the vertebral groove, and lodges the origin of the Multifidus spine.

**Lateral Surface.**—The lateral surface, broad above, becomes narrowed into a thin edge below. Its upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the auricular surface \((\text{facies auricularis})\), and in the fresh state is coated with fibro-cartilage. It is bounded posteriorly by deep and uneven impressions, for the attachment of the posterior sacro-iliac ligaments. The chief prominence is called the tuberosity \((\text{tuberositas sacralis})\). The lower half is thin and sharp, and terminates in a projection called the inferior lateral angle; below this angle is a notch, which is converted into a foramen by articulation with the transverse process of the upper piece of the coccyx, and transmits the anterior division of the fifth sacral nerve. This lower, sharp border gives attachment to the greater and lesser sacro-sciatic ligaments, and to some fibres of the Gluteus maximus posteriorly, and to the Coccygeus in front.
Base (basis oss. sacri).—The base of the sacrum, which is broad and expanded, is directed upward and forward. In the middle is seen a large oval articular surface, which is connected with the under surface of the body of the last lumbar vertebra by a fibro-cartilaginous disk. It is bounded behind by the large, triangular orifice of the sacral canal. The orifice is formed behind by the laminae and spinous process of the first sacral vertebra: the superior articular processes project from it on each side; they are oval, concave, directed backward and inward, like the superior articular processes of a lumbar vertebra; and in front of each articular process is an intervertebral notch, which forms the lower part of the foramen between the last lumbar and first sacral vertebra. Lastly, on each side of the large oval articular plate is a broad and flat triangular surface of bone, which extends outward, supports the Psoas magnus muscle and lumbo-sacral cord, and is continuous on each side with the iliac fossa. This is called the ala of the sacrum (ala sacralis), and gives attachment to a few of the fibres of the Iliacus muscle. The posterior part of the ala represents the transverse process of the first sacral segment.

Apex (apex oss. sacri).—The apex, directed downward and slightly forward, presents a small, oval, concave surface for articulation with the coccyx.

Spinal Canal.—The spinal canal in this region is called the sacral canal (canalis sacralis). It runs throughout the greater part of the bone; it is large and triangular in form above, small and flattened, from before backward, below. In this situation its posterior wall is incomplete, from the non-development of the laminae and spinous processes (hiatus sacralis). It lodges the sacral nerves, and is perforated by the anterior and posterior sacral foramina, through which these pass out.

Structure.—It consists of much loose, spongy tissue within, invested externally by a thin layer of compact tissue.

Differences in the Sacrum of the Male and Female.—The sacrum in the female is shorter and wider than in the male; the lower half forms a greater angle with the upper, the upper half of the bone being nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backward, which increases the size of the pelvic cavity; but the sacro-vertebral angle projects less. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Peculiarities of the Sacrum.—This bone, in some cases, consists of six pieces; occasionally, the number is reduced to four. Sometimes the bodies of the first and second segments are not joined or the laminae and spinous processes have not coalesced. Occasionally, the upper pair of transverse tubercles are not joined to the rest of the bone on one or both sides; and, lastly, the sacral canal may be open for nearly the lower half of the bone, in consequence of the imperfect development of the laminae and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature. From the examination of a large number of skeletons it would appear that in one set of cases the anterior surface of this bone was nearly straight, the curvature, which was very slight, affecting only its lower end. In another set of cases the bone was curved throughout its whole length, but especially toward its middle. In a third set the degree of curvature was less marked, and affected especially the lower third of the bone.

Development (Fig. 33).—The sacrum, formed by the union of five vertebrae, has thirty-five centres of ossification.

The bodies of the sacral vertebrae have each three ossific centres: one for the central part, and one for the epiphysial plates on its upper and under surface. Occasionally the primary centres for the bodies of the first and second piece of the sacrum are double.
The arch of each sacral vertebra is developed by two centres, one for each lamina. These unite with each other behind, and subsequently join the body.

The lateral masses have six additional centres, two for each of the first three vertebrae. These centres make their appearance above and to the outer side of the anterior sacral foramina (Fig. 33), and are developed into separate segments (Fig. 34); they are subsequently blended with each other, and with the bodies and transverse processes to form the lateral mass.

Lastly, each lateral surface of the sacrum is developed by two epiphysial plates (Fig. 35): one for the auricular surface, and one for the remaining part of the thin lateral edge of the bone.

**Fig. 33.—Development of the sacrum.**

**Fig. 34.**

**Fig. 35.**

**Period of Development.**—At about the eighth or ninth week of foetal life ossification of the central part of the bodies of the first three vertebrae commences, and at a somewhat later period that of the last two. Between the sixth and eighth months ossification of the laminae takes place; and at about the same period the centres for the lateral masses for the first three sacral vertebrae make their appearance. The period at which the arch becomes completed by the junction of the laminae with the bodies in front and with each other behind varies in different segments. The junction between the laminae and the bodies takes place first in the lower vertebrae as early as the second year, but is not affected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphyses for the upper and under surfaces of the bodies are formed, and between the eighteenth and twentieth years those for each lateral surface of the sacrum make their appearance. The bodies of the sacral vertebrae are, during early life, separated from each other by intervertebral disks. But about the eighteenth year the two lowest segments become joined together by ossification extending through the disk. This process gradually extends upward until all the segments become united, and the bone is completely formed from the twenty-fifth to the thirtieth year of life.

**Articulations.**—With four bones: the last lumbar vertebra, coccyx, and the two innominate bones.

**Attachment of Muscles.**—To eight pairs: in front, the Pyriformis and Coccygeus, and a portion of the Iliacus to the base of the bone; behind, the Gluteus maximus, Latissimus dorsi, Multifidus spine, and Erector spine, and sometimes the Extensor coccygis.

**Coccyx (os coccygis).**—The coccyx (kók'æ, cuckoo), so called from having been compared to a cuckoo’s beak (Fig. 36), is usually formed of four small segments of bone, the most rudimentary parts of the vertebral column (vertebrae coccygeae or caudate vertebrae). In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (some-
times the third) is a mere nodule of bone, without distinct processes. All the segments are destitute of pedicles, lamine, and spinous processes, and, consequently, of intervertebral foramina and spinal canal. The first segment is the largest; it resembles the lowermost sacral vertebra, and often exists as a separate piece; the last three, diminishing in size from above downward, are usually blended together so as to form a single bone. The gradual diminution in the size of the pieces gives this bone a triangular form, the base of the triangle joining the end of the sacrum. It presents for examination an anterior and posterior surface, two borders, a base, and an apex.

**Surfaces. Anterior Surface.**—The anterior surface is slightly concave, and marked with three transverse grooves, indicating the points of junction of the different pieces. It has attached to it the anterior sacro-coccygeal ligament and Levator ani muscle, and supports the lower end of the rectum.

**Posterior Surface.**—The posterior surface is convex, marked by transverse grooves similar to those on the anterior surface; and presents on each side a lineal row of tubercles, the rudimentary articular processes of the coccygeal vertebrae. Of these, the superior pair are large, and are called the *cornua of the coccyx* (*cornua coecygea*); they project upward, and articulate with the cornua of the sacrum, the junction between these two bones completing the fifth posterior sacral foramen for the transmission of the posterior division of the fifth sacral nerve.

**Borders.**—The lateral borders are thin, and present a series of small eminences, which represent the transverse processes of the coccygeal vertebrae. Of these, the first on each side is the largest, flattened from before backward, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downward, and are often wanting. The borders of the coccyx are narrow, and give attachment on each side to the sacro-sciatic ligaments, to the Coccygeus muscles in front of the ligaments, and to the Gluteus maximus behind them.

**Base.**—The base presents an oval surface for articulation with the sacrum. This articulation is known as the *sacro-coccygeal symphysis* (*symphysis sacro-coccygea*).

**Apex.**—The apex is rounded, and has attached to it the tendon of the external Sphincter muscle. It is occasionally bifid, and sometimes deflected to one or other side.

**Development.**—The coccyx is developed by *four* centres, one for each piece. Occasionally one of the first three pieces of this bone is developed by two centres, placed side by side. The ossific nuclei make their appearance in the following order: in the first segment, shortly after birth; in the second piece, at from five...
to ten years; in the third, from ten to fifteen years; in the fourth, from fifteen to twenty years. As age advances these various segments become united with each other from below upward, the union between the first and second segments being frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in females, the coccyx often becomes joined to the end of the sacrum.

**Articulation.**—With the sacrum.

**Attachment of Muscles.**—To four pairs and one single muscle: on either side, the Coccygeus; behind, the Gluteus maximus and Extensor coccygis, when present; at the apex, the Sphincter ani; and in front, the Levator ani.

### The Vertebral Column or Spine in General.

The spinal column (*columna vertebralis*), formed by the junction of the vertebrae, is situated in the median line, at the posterior part of the trunk; its average length is about two feet two or three inches, measuring along the curved anterior surface of the column. Of this length the cervical part measures about five, the dorsal about eleven, the lumbar about seven inches, and the sacrum and coccyx the remainder. The female spine is about one inch less than that of the male.

Viewed in front, the ventral surface presents two pyramids joined together at their bases, the upper one being formed by all the vertebrae from the second cervical to the last lumbar, the lower one by the sacrum and coccyx. When examined more closely, the upper pyramid is seen to be formed of three smaller pyramids. The uppermost of these consists of the six lower cervical vertebrae, its apex being formed by the axis or second cervical, its base by the first dorsal. The second pyramid, which is inverted, is formed by the four upper dorsal vertebrae, the base being at the first dorsal, the smaller end at the fourth. The third pyramid commences at the fourth dorsal, and gradually increases in size to the fifth lumbar.

Viewed laterally (Fig. 37), the spinal column presents several curves which correspond to the different regions of the column, and are called cervical, dorsal, lumbar, and pelvic. The **cervical curve** commences at the apex of the odontoid process, and terminates at the
middle of the second dorsal vertebra; it is convex in front, and is the least marked of all the curves. The dorsal curve, which is concave forward, commences at the middle of the second, and terminates at the middle of the twelfth dorsal vertebra. Its most prominent point behind corresponds to the spine of the seventh dorsal vertebra. The lumbar curve commences at the middle of the last dorsal vertebra, and terminates at the sacro-vertebral angle. It is convex anteriorly; the convexity of the lower three vertebrae being much greater than that of the upper two. The pelvic curve commences at the sacro-vertebral articulation and terminates at the point of the coccyx. It is concave anteriorly. The dorsal and pelvic curves are the primary curves, and begin to be formed at an early period of foetal life, and are due to the shape of the bodies of the vertebrae. The cervical and lumbar curves are compensatory or secondary, and are developed after birth in order to maintain the erect position. They are due mainly to the shape of the intervertebral disks.

Some writers teach that the spine has a normal deviation to the right side. Quain, Hyrtl, and others maintain this view. The curve is said to be in the dorsal region. Bichat assigned muscular action as the chief cause of the curve. Most persons use the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation is the observation made by Béclard that in some individuals who were left-handed the lateral curvature was directed to the left side. Sappey and others deny the existence of this curve.

The movable part of the spinal column presents for examination an anterior, a posterior, and two lateral surfaces; a base, a summit, and the spinal canal.

Surfaces. Anterior Surface.—The anterior or ventral surface presents the bodies of the vertebrae separated in the recent state by the intervertebral disks. The bodies are broad in the cervical region, narrow in the upper part of the dorsal, and broadest in the lumbar region. The whole of this surface is convex transversely, concave from above downward in the dorsal region, and convex in the same direction in the cervical and lumbar regions.

Posterior Surface.—The posterior or dorsal surface presents in the median line the spinous processes. These are short, horizontal, with bifid extremities, in the cervical region. In the dorsal region they are directed obliquely above, assume almost a vertical direction in the middle, and are horizontal below, as are also the spines of the lumbar vertebrae. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the dorsal region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the spine. On either side of the spinous processes, extending the whole length of the column, is the vertebral groove formed by the laminae in the cervical and lumbar regions, where it is shallow, and by the laminae and transverse processes in the dorsal region, where it is deep and broad. In the recent state these grooves lodge the deep muscles of the back. External to each vertebral groove are the articular processes, and still more externally is the transverse process. In the dorsal region the latter processes stand backward, on a plane considerably posterior to the same processes in the cervical and lumbar regions. In the cervical region the transverse processes are placed in front of the articular processes, and on the outer side of the pedicles, between the intervertebral foramina. In the dorsal region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar region they are placed also in front of the articular processes, but behind the intervertebral foramina.

Lateral Surfaces.—The lateral surfaces are separated from the posterior surface by the articular processes in the cervical and lumbar regions, and by the trans-
verse processes in the dorsal region. These surfaces present in front the sides of the bodies of the vertebra, marked in the dorsal region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the dorsal regions, and gradually increasing in size to the last lumbar vertebra. They are situated between the transverse processes in the neck, and in front of them in the back and loins, and transmit the spinal nerves.

**Base.**—The base of that portion of the vertebral column formed by the twenty-four movable vertebrae is formed by the under surface of the body of the fifth lumbar vertebra; and the **summit** by the upper surface of the atlas.

**Spinal Canal (canalis vertebralis).**—The vertebral or spinal canal follows the different curves of the spine; it is largest in those regions in which the spine enjoys the greatest freedom of movement, as in the neck and loins, where it is wide and triangular; and is narrow and rounded in the back, where motion is more limited. The centre of gravity of the spine is in the upper lumbar region, slightly to the right of the median plane (Struthers).

**Surface Form.**—The only parts of the vertebral column which lie closely under the skin, and so directly influence surface form, are the apices of the spinous processes. These are always distinguishable at the bottom of a median furrow, which, more or less evident, runs down the mesial line of the back from the external occipital protuberance above to the middle of the sacrum below.

In the cervical region the furrow is between the Trapezius muscles; in the back and loins it is between the Erector spine muscles. In the neck the furrow is broad, and terminates in a conspicuous projection, which is caused by the spinous process of the seventh cervical vertebra (vertebra prominens). Above this the spinous process of the sixth cervical vertebra may sometimes be seen to form a projection; the other cervical spines are sunken, and are not visible, though the spine of the axis can be felt, and generally also the spines of the third, fourth, and fifth cervical vertebrae. In the dorsal region the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible. The markings produced by these spines are small and close together. In the lumbar region the furrow is deep, and the situation of the lumbar spines is frequently indicated by little pits or depressions, especially if the muscles in the loins are well developed and the spine incurved. They are much larger and farther apart than in the dorsal region. In the sacral region the furrow is shallower, presenting a flattened area which terminates below at the most prominent part of the posterior surface of the sacrum, formed by the spinous process of the third sacral vertebra. At the bottom of the furrow may be felt the irregular posterior surface of the bone. Below this, in the deep groove leading to the anus, the coccyx may be felt. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebrae—viz., the first, the sixth, and the seventh. The transverse process of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, along the anterior border of the sternomastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck in the course of the carotid artery, opposite the ericoid cartilage, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra can be felt. This has been named **Chassaignac's tubercle**, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can also often be felt. Occasionally the anterior root, or costal process, is large and segmented off, forming a cervical rib.

**Surgical Anatomy.**—It is frequently necessary to locate certain vertebrae. Several of them can be easily found and identified. The seventh cervical spine is conspicuously prominent, and when the skin above it has been marked with a blue pencil the spine of the sixth cervical above and of the first dorsal below may be located. The spine of the third dorsal vertebra is on a level with the root of the spine of the scapula. The spine of the fourth lumbar vertebra is on a level with the highest point of the iliac crest. When one or two vertebrae have been definitely recognized the other ones can be found by counting the spines from a fixed point or from fixed points. Over the fifth lumbar spine there is no prominence, but a depression. The third sacral spine is on a level with the posterior superior spines of the ilium. The level at which the spinal cord terminates should be known to the surgeon if he proposes to tap the dural sac (lumbar puncture), for diagnostic or therapeutic purposes or as a preliminary to the injection of cocaine or eucaine (spinal anaesthesia). In an adult the cord terminates at the lower border of the first lumbar vertebra, and the dural sac terminates opposite the body of the third sacral vertebra. In a child the cord terminates opposite the body of the third lumbar vertebra, and the dural sac ends at
about the same level as in an adult. Hence, in either a child or an adult, a puncture below the level of the fourth lumbar vertebra will inflict no injury upon the cord. In children the puncture is made just beneath the vertebral spine, and in adults about one-half an inch to either side of the vertebral spine, although, even in adults, the needle is made to enter the dura in the middle line. In either case the needle is directed upward and forward. As previously pointed out, the surgical anatomy of an infant’s spine is not identical with the surgical anatomy of an adult’s spine. An infant’s spine is larger comparatively than an adult’s spine, because the lower limbs are less developed in the former (A. H. Tubby). The umbilicus of an infant is opposite the body of the fourth lumbar vertebra; in an adult it is opposite the spine of the third lumbar vertebra. In an infant the base of the sternum is on a level with the top of the seventh cervical spine, and in an adult of the second dorsal spine (A. H. Tubby).

Occasionally the coalescence of the laminae is not completed, and consequently a cleft is left in the arches of the vertebrae, through which a protrusion of the spinal membranes (dura mater and arachnoid), and sometimes of the spinal cord itself, takes place, constituting a malformation known as spina bifida or hydrocephalus. This disease is most common in the lumbo-sacral region; but it may occur in the dorsal or cervical region, or the arches throughout the whole length of the canal may remain unapproximated. In some rare cases, in consequence of the non-coalescence of the two primary centres from which the body is formed, a similar condition may occur in front of the canal, the bodies of the vertebrae being found cleft and the tumor projecting into the thorax, abdomen, or pelvis, between the lateral halves of the bodies affected.

The construction of the spinal column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, though permitting of a very considerable range of movement as a whole, allows a sufficient degree of mobility without any material diminution of strength. The main joints of which the spine is composed, together with the very varied movements to which it is subjected, render it liable to sprains, which may complicate other injuries or may exist alone; but so closely are the individual vertebrae articulated that these sprains are seldom severe, and an amount of violence sufficiently great to produce tearing of the ligaments would tend to cause a dislocation or fracture. The further safety of the column and its less liability to injury is provided for by its disposition in curves instead of in one straight line. For it is an elastic column, and must first bend before it breaks: under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one that is equal to it in breadth and material. Again, the safety of the column is provided for by the interposition of the intervertebral disks between the bodies of the vertebrae, which act as admirable buffers in counteracting the effects of violent jars or shocks. Fracture dislocation of the spine may be caused by direct or indirect violence, or by a combination of the two, as when a person, falling from a height, strikes against some prominence and is doubled over it. The fractures from indirect violence are the more common, and here the bodies of the vertebrae are compressed, whilst the arches are torn asunder; whilst in fractures from direct violence the arches are compressed and the bodies of the vertebrae separated from each other. It will therefore be seen that in both classes of injury the spinal marrow is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. For, as Mr. Jacobson states, "being lodged in the centre of the column, it occupies neutral ground in respect to forces which might cause fracture. For it is a law in mechanics that when a beam, as of timber, is exposed to breakage and the force does not exceed the limits of the strength of the material, one division resists compression, another laceration of the particles, while the third, between the two, is in a negative condition." Applying this principle to the spine it will be seen that, whether the fracture dislocation be produced by direct violence or by indirect force, one segment, either the anterior or posterior, will be exposed to compression, the other to laceration, and the intermediate part, where the cord is situated, will be in a neutral state. When a fracture dislocation is produced by indirect violence the displacement is almost always the same, the upper segment being driven forward on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

The parts of the spine most liable to be injured are (1) the dorso-lumbar region, for this part is near the middle of the column, and there is therefore a greater amount of leverage, and moreover the portion above is comparatively fixed, and the vertebrae which form it, though much smaller, have nevertheless to bear almost as great a weight as those below; (2) the cervico-dorsal region, because here the flexible cervical portion of the spine joins the more fixed dorsal region; and (3) the atlanto-axial region, because it enjoys an extensive range of movement, and, being near the skull, is influenced by violence applied to the head. In fracture dislocation spinous processes and portions of the laminae may be removed (laminectomy) in order to free the cord from pressure, and to permit the surgeon to explore, to arrest hemorrhage, to remove bone fragments, or to apply sutures. Laminectomy is also resorted to in some cases of paraplegia due to Pott's disease of the spine.

1 Holmes's System of Surgery, vol. i. p. 529, 1883.
THE SKULL.

The skeleton of the head is called the skull. The cranium is the skull without the mandible. The calvaria or cerebral cranium is the skull without the bones of the face. The skull is supported on the summit of the vertebral column, and is of an oval shape, wider behind than in front. It is composed of a series of flattened or irregularly shaped bones which, with one exception (the lower jaw), are immovably joined together. It is divided into two parts, the cerebral cranium or calvaria and the visceral cranium or face, the former of which constitutes a case for the accommodation and protection of the brain, while opening on the face are the orifices of the nose and mouth; between the cerebral cranium above and the face below the orbital cavities are situated. The cerebral cranium (ξρινας, a helmet) is composed of eight bones—viz., the occipital, two parietal, frontal, two temporal, sphenoid, and ethmoid. The face is composed of fourteen bones—viz., the two nasal, two superior maxillary, two lachrymal, two malar, two palate, two inferior turbinated, vomer, and inferior maxillary or mandible. The ossiculi auditus, the teeth, and Wormian bones are not included in this enumeration.

The Hyoid Bone, situated at the root of the tongue and attached to the base of the skull by ligaments, has also to be considered in this section.

THE CEREBRAL CRANIUM (CRANIUM CEREBRALE) (THE CALVARIA).

The Occipital Bone (Os Occipitale).

The occipital bone (ob, caput, against the head) is situated at the back part and base of the cranium, is trapezoid in shape and is much curved on itself (Fig. 38). It presents at its front and lower part a large oval aperture, the foramen magnum (foramen occipitale magnum), by which the cranial cavity communicates with the spinal canal. The portion of bone behind this opening is flat and expanded and forms the tabula, tabular portion, or squamous part (squama occipitalis); the portion in front is a thick, elongated mass of bone, the basilar process (pars basilaris); while on each side of the foramen is situated a lateral or condylie portion (pars lateralis), bearing the condyle, by which the bone articulates with the atlas. The bone presents for examination two surfaces, four borders, and four angles.

Surfaces. External Surface.—The external surface is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum is a prominent tubercle, the inion or external occipital protuberance (protuberantia
occipitalis externa, and, descending from it as far as the foramen, a vertical ridge, the external occipital crest (crista occipitalis externa). This protuberance and crest give attachment to the ligamentum nuchae, and vary in prominence in different skulls. Passing outward from the occipital protuberance is a semicircular ridge on each side, the superior curved or superior nuchal line (linea nuchae superior). Above this line there is often a second less distinctly marked ridge, called the highest curved line (linea nuchae suprema); to it the epocranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge on each side, the inferior curved or inferior nuchal line (linea nuchae inferior). The surface of the bone above the linea suprema is rough and porous, and in the recent state is covered by the

Occipito-frontalis muscle. It is called the occipital portion or the planum occipitale. The superior and inferior curved lines, together with the surfaces of bone between and below them, serve for the attachment of several muscles. The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipito-frontalis, and to the Sterno-cleido-mastoid to the extent shown in Fig. 38; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line and the depressions below it afford insertion to the Rectus capitis posticus, major and minor. The portion of the tabula below the superior curved line is called the nuchal plane (planum nuchale), and it gives attachment to certain of the neck muscles.

The foramen magnum (foramen occipitale magnum) is a large, oval aperture, its long diameter extending from before backward. It transmits the lower portion
of the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. Its back part is wide for the transmission of the medulla, and the corresponding margin rough for the attachment of the dura mater enclosing it; the fore part is narrower, being encroached upon by the condyles; it has projecting toward it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. The middle of the anterior wall of the foramen magnum is called by Broca the basion. The lateral or condylar portions (partes laterales) are on either side of the foramen magnum and bear the condyles for articulation with the atlas. Each condyle (condylus occipitalis) is convex, oval, or reniform in shape, and directed downward and outward. The condyles converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the ligaments (cheek) which connect this bone with the odontoid process of the axis; while external to them is a rough tubercular prominence, the transverse or jugular process (processus jugularis), channelled in front by a deep notch (incisura jugularis), which forms part of the jugular foramen or foramen lacerum posticus. The under surface of this process presents an eminence (processus intrajugularis) which represents the paramastoid process of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipito-atlantal ligament; its upper or cerebral surface presents a deep groove which lodges part of the lateral sinus, while its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the anterior condyloid foramen (canalis hypoglossi or the hypoglossal canal); it is directed downward, outward, and forward, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa¹ (fossa condyloideus), sometimes perforated at the bottom by a foramen, the posterior condyloid foramen (canalis condyloideus), for the transmission of a vein to the lateral sinus. The basilar process (pars basilaris) is a strong quadrilateral plate of bone, which is wider behind than in front, and is situated in front of the foramen magnum. Its under surface, which is rough, presents in the median line a tubercular ridge, the pharyngeal spine or tubercle (tuberculum pharyngeum), for the attachment of the tendinous raphé and Superior constrictor of the pharynx; and on each side of it rough depressions for the attachment of the Rectus capitis anticus, major and minor.

Internal Surface.—The internal or cerebral surface (Fig. 39) is deeply concave. The posterior or tabular part is divided by a crucial ridge into four fossae. The two superior fossae receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgement of arteries. At the point of meeting of the four divisions of the crucial ridge is an eminence, the internal occipital protuberance (protuberantia occipitalis interna). It nearly corresponds to that on the outer surface, though it is often on a slightly higher level, and is perforated by one or more large vascular foramina. From this eminence the superior division of the crucial ridge runs upward to the superior angle of the bone; it presents a deep groove, the sagittal sulcus (sulcus sagit-

¹ This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.
talis), for the superior longitudinal sinus. The margins of the groove give attachment to the falx cerebri. The inferior division, the internal occipital crest (crista occipitalis interna), runs to the posterior margin of the foramen magnum, on the edge of which it becomes gradually lost; this ridge, which is bifurcated below, serves for the attachment of the falx cerebelli. It is usually marked by a single groove, which commences at the back part of the foramen magnum and lodges the occipital sinus. Occasionally the groove is double where two sinuses exist. A transverse groove (sulcus transversus) passes outward on each side to the lateral angle. The grooves are deep channels for the lodgement of the lateral sinuses, their prominent margins affording attachment to the tentorium cerebelli.\(^1\) At the point of meeting of these grooves is a depression, the torcular Herophili,\(^2\) placed a little to one or the other side of the internal occipital protuberance. More anteriorly is the foramen magnum, and on each side of it, but nearer its anterior than its posterior part, the internal openings of the anterior condyloid foramen. On the superior aspect of the lateral portion of the bone the jugular tubercle (tuberculum jugulare) is seen. This corresponds to the portion of bone which roofs in the anterior condyloid foramen. The internal openings of the posterior condyloid

\(^1\) Usually one of the transverse grooves is deeper and broader than the other; occasionally, both grooves are of equal depth and breadth, or both equally indistinct. The broader of the two transverse grooves is nearly always continuous with the vertical groove for the superior longitudinal sinus.

\(^2\) The columns of blood coming in different directions were supposed to be pressed together at this point (torcular, a wine-press).
foramina are a little external and posterior to the openings of the anterior condyloid foramina, protected by a small arch of bone. At this part of the internal surface there is a very deep groove in which the posterior condyloid foramen, when it exists, has its termination. This groove is continuous, in the complete skull, with the transverse groove on the posterior part of the bone, and lodges the end of the same sinus, the lateral. In front of the foramen magnum is the basilar process, presenting a shallow depression, the basilar groove (clivus), which slopes from behind, upward and forward, and supports the medulla oblongata and part of the pons Varolii, and on each side of the basilar process is a narrow channel, which, when united with a similar channel on the petrous portion of the temporal bone, forms a groove (sulcus petrosus inferior) which lodges the inferior petrosum sinus.

**Borders. Superior Border.**—The superior border, lambdoidal margin (margo lambdoideus), extends on each side from the superior to the lateral angle, is deeply serrated for articulation with the parietal bone, and forms, by this union, the lambdoid suture.

**Inferior Border.**—The inferior border extends from the lateral to the inferior angle; its upper half, mastoid margin (margo mastoideus), is rough, and articulates with the mastoid portion of the temporal, forming the masto-occipital suture; the inferior half articulates with the petrous portion of the temporal, forming the petro-occipital suture; these two portions are separated from one another by the jugular process. In front of this process is a deep notch, which, with a similar one on the petrous portion of the temporal, forms the jugular foramen (foramen lacerum posteiuris). This notch is occasionally subdivided into two parts by a small process of bone (processus intrajugularis), and it generally presents an aperture at its upper part, the internal opening of the posterior condyloid foramen.

**Angles. Superior Angle.**—The superior angle is received into the interval between the posterior superior angles of the two parietal bones; it corresponds with that part of the skull in the fetus which is called the posterior fontanelle (lambda).

**Inferior Angle.**—The inferior angle is represented by the square-shaped surface of the basilar process. At an early period of life a layer of cartilage separates this part of the bone from the sphenoid, but in the adult the union between them is osseous.

**Lateral Angles.**—The lateral angles correspond to the outer ends of the transverse grooves, and are received into the interval between the posterior inferior angles of the parietal and the mastoid portion of the temporal. The junction of the occipital, parietal, and temporal bones was named the asterion by Broca.

**Structure.**—The occipital bone consists of two compact lamina, called the outer and inner tables, having between them the diploic tissue; this bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar process; while at the bottom of the fosse, especially the inferior, it is thin, semitransparent, and destitute of diploë.

**Development** (Fig. 40).—At birth the bone consists of four distinct parts: a tabular squamous or expanded portion, which lies behind the foramen magnum; two condylic parts, which form the sides of the foramen; and a basilar part, which lies
in front of the foramen. The number of nuclei for the tabular part vary. As a rule, there are four, but there may be only one (Blandin) or as many as eight (Meckel). They appear about the eighth week of foetal life, and soon unite to form a single piece, which is, however, fissured in the direction indicated in Fig. 40. The basilar and two condyloid portions are each developed from a single nucleus, which appears a little later. The upper portion of the tabular surface—that is to say, the portion above the transverse fissure—is developed from membrane, and may remain separated from the rest of the bone throughout life, when it constitutes the interparietal bone, which is called the os incae, because of its frequent occurrence in Peruvian skulls. The rest of the bone is developed from cartilage. At about the fourth year the tabular and the two condyloid pieces join, and about the sixth year the bone consists of a single piece. At a later period, between the eighteenth and twenty-fifth years, the occipital and sphenoid become united, forming a single bone.

Articulations.—With six bones: two parietal, two temporal, sphenoid, and atlas.

Attachment of Muscles.—To twelve pairs: to the superior curved line are attached the Occipito-frontalis, Trapezius, and Sterno-cleido-mastoid. To the space between the curved lines, the Complexus,1 Splenius capitis, and Obliquus capitis superior; to the inferior curved line, and the space between it and the foramen magnum, the Rectus capitis posticus, major and minor; to the transverse process, the Rectus capitis lateralis; and to the basilar process, the Rectus capitis anticus, major and minor, and Superior constrictor of the pharynx.

The Parietal Bone (Os Parietale).

The parietal bones (paries, a wall) are paired bones and form, by their union, the sides and roof of the cerebral cranium. Each bone is of an irregular quadrilateral form, and presents for examination two surfaces, four borders, and four angles.

Surfaces. External Surface (facies parietalis).—The external surface (Fig. 41) is convex, smooth, and marked about its centre by an eminence called the parietal eminence (tuber parietale), which indicates the point where ossification commenced. Crossing the middle of the bone in an arched direction are two well-marked curved lines or ridges, the upper and lower temporal lines or ridges (linea temporalis superior et inferior); the former gives attachment to the temporal fascia, while the latter indicates the upper limit of the origin of the Temporal muscle. These lines form the temporal crest. Above these ridges the surface of the bone is rough and porous, and covered by the aponeurosis of the Occipito-frontalis; between them the bone is smoother and more polished than the rest; below them the bone forms part of the temporal fossa. This portion of bone is called the planum temporale, and affords attachment to the Temporal muscle. The superior stephanion is the intersection of the upper temporal ridge with the coronal suture. The inferior stephanion is the intersection of the lower temporal ridge with the coronal suture. At the back part of the superior border, close to the sagittal suture, is a small foramen, the parietal foramen (foramen parietale), which transmits the emissary vein of Santorini from the scalp to the superior longitudinal sinus. It sometimes also transmits a small branch of the occipital artery. Its existence is not constant, and its size varies considerably. The point on the sagittal suture, between the parietal foramina, is the obelion.

Internal or Cerebral Surface (facies cerebralis).—The internal surface (Fig. 42) is concave, presents depressions for lodging the convolutions of the cerebrum and numerous furrows, for the ramifications of the middle meningeal artery; the

latter runs upward and backward from the anterior inferior angle and from the central and posterior part of the lower border of the bone. The depression for the middle meningeal artery at the anterior and inferior portions of the cerebral surface of the bone is called the sulcus arteriosus. Sometimes a distinct canal exists for the artery, but it never remains a canal for a long distance. Along the upper margin of the bone is part of a shallow groove, which, when joined to the opposite parietal, forms a channel for the superior longitudinal sinus (the sulcus sagittalis). The elevated edges of the groove afford attachment to the falx cerebri. Near the groove are seen several depressions, Pacchionian depressions (foveola granulares [Pacchioni]). They are most frequently found in the skulls of old persons, and lodge the Pacchionian bodies. The internal opening of the parietal foramen is also seen when that aperture exists. On the inner surface of the posterior inferior portion of the bone is a portion of the groove for the lodgment of the lateral sinus (sulcus transversus).

**Borders.** **Superior Border.**—The superior border, sagittal margin (margo sagittalis), the longest and thickest, is dentated to articulate with its fellow of the opposite side, forming the sagittal suture.

**Inferior Border.**—The inferior border, squamous margin (margo squamosus), is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squamous portion of the temporal; the posterior portion is thick and serrated for articulation with the mastoid portion of the temporal.

**Anterior Border.**—The anterior border, frontal margin (margo frontalis), deeply serrated, is bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming the coronal suture.

**Posterior Border.**—The posterior border, occipital margin (margo occipitalis), deeply denticulated, articulates with the occipital, forming the lambdoid suture.

**Angles.** **Anterior Superior Angle** (angulus frontalis).—The anterior superior or frontal angle, thin and pointed, corresponds with that portion of the skull which in the foetus is membranous, and is called the anterior fontanelle (bregma).

**Anterior Inferior Angle** (angulus sphenoidalis).—The anterior inferior or sphenoidal angle is thin and lengthened, being received in the interval between the great wing of the sphenoid and the frontal. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. At the anterior inferior angle the parietal, temporal, and frontal bones and the greater wing of the sphenoid bone meet. This spot is called the pterion.

**Posterior Superior Angle** (angulus occipitalis).—The posterior superior or occipital angle corresponds with the junction of the sagittal and lambdoid sutures. In the foetus this part of the skull is membranous, and is called the posterior fontanelle (lambda).

**Posterior Inferior Angle** (angulus mastoideus).—The posterior inferior or mastoid angle articulates with the mastoid portion of the temporal bone, and generally presents on its inner surface a broad, shallow groove for lodging part of the lateral sinus.

**Development.**—The parietal bone is formed in membrane, being developed by one centre, which corresponds with the parietal eminence, and makes its first appearance about the seventh or eighth week of foetal life. Ossification gradually extends from the centre to the circumference of the bone: the angles are consequently the parts last formed, and it is in their situation that the fontanelles exist previous to the completion of the growth of the bone. Occasionally the parietal bone is divided into two parts, upper and lower, by an antero-posterior suture.
Articulations.—With five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

Attachment of Muscles.—One only, the Temporal.

The Frontal Bone (Os Frontale).

The frontal bone (frons, the forehead) resembles a cockle-shell in form, and consists of two portions—a vertical or frontal portion, situated at the anterior part of the cranium, forming the forehead; and a horizontal or orbital portion, which enters into the formation of the roof of the orbits and nasal fossae.

Vertical Portion of the Frontal Bone (Pars Frontalis).

Surfaces. External Surface (facies frontalis) (Fig. 43).—In the median line, traversing the bone from the upper to the lower part, is occasionally seen a slightly elevated ridge, and in young subjects a suture, the frontal (metopic) suture, which represents the line of union of the two lateral halves of which the bone consists at an early period of life; in the adult this suture is usually obliterated and the bone forms one piece; traces of the obliterated suture are, however, generally perceptible at the lower part. On either side of this ridge, a little below the centre of the bone, is a rounded eminence, the frontal eminence (tuber frontale). These eminences vary in size in different individuals, and are occasionally unsymmetrical in the same subject. They are especially prominent in cases of well-marked cerebral development. The whole surface of the bone above this part is smooth, and covered by the aponeurosis of the Occipitofrontalis muscle. Below the frontal eminence and separated from it by a slight
groove is the **superciliary ridge** (*arcus superciliaris*), broad internally, where it is continuous with the nasal eminence, but less distinct as it arches outward. These ridges are caused by the projection outward of the frontal air sinuses,¹ and give attachment to the Orbicularis palpbrarum and Corrugator supercili. Between the two superciliary ridges is a smooth, flat surface, the **glabella**. Nearly corresponding with the glabella is the **ophryon**, a point in the mid-line on a level with the upper border of the eyebrows, which is the centre of the narrowest transverse diameter of the forehead. Beneath the superciliary ridge is the **orbital margin** or **supraorbital arch** (*margo supraorbitale*), a curved and prominent margin, which forms the upper boundary of the orbit and separates the vertical from the horizontal portion of the bone. The outer part of the arch is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the inner part is less prominent. At the junction of the internal and middle third of this arch is a notch, sometimes converted into a foramen, and called the **supraorbital notch** or **foramen** (*incisura supraorbitalis or foramen supraorbitale*). It transmits the supraorbital artery, vein, and nerve. A small aperture is seen in the upper part of the notch, which transmits a vein from the diploë to join the supraorbital vein. To the median side of the supraorbital notch there is often a notch (*incisura frontalis*) for the passage of the frontal artery and frontal nerve. The supraorbital arch terminates externally in the **external angular process** (*processus zygomaticus*) and internally in the **internal angular process**. The external angular process is strong, prominent, and articulates with the malar bone; running upward and backward from it are two well-marked lines, which, commencing together from the external angular process as the **temporal ridge, crest or line** (*linea temporalis*), soon divide from each other and run in a curved direction across the bone. These are the **upper and lower temporal ridges**; the upper gives attachment to the temporal fascia, the lower to the Temporal muscle. Beneath them is a slight concavity that forms the anterior part of the temporal fossa and gives origin to the Temporal muscle. The internal angular processes are less marked than the external, and articulate with the lachrymal bones. Between the internal angular processes is a rough, uneven interval, the **nasal notch**, which articulates in the middle line with the nasal bone, and on either side with the nasal process of the superior maxillary bone. From the concavity of this notch projects a process, the **nasal process**, which extends beneath the nasal bones and nasal processes of the superior maxillary bones and supports the bridge of the nose. On the under surface of this is a long, pointed process, the **nasal or frontal spine** (*spina nasalis or frontalis*), and on either side a small grooved surface enters into the formation of the roof of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the nasal bones and behind with the perpendicular plate of the ethmoid. The junction of the nasal and frontal bones is called the **nasion**.

**Internal Surface** (*cerebral surface, facies cerebralis*) (Fig. 44).—Along the middle line is a vertical groove, the **sulcus sagittalis**, the edges of which unite below to form a ridge, the **frontal crest** (*crista frontalis*); the groove lodges the superior longitudinal sinus, whilst its margins afford attachment to the falx cerebri. The crest terminates below at a small notch which is converted into a foramen by articulation with the ethmoid. It is called the **foramen cecum**, and varies in size in different subjects: it is sometimes partially or completely impervious,

¹ Some confusion is occasioned to students commencing the study of anatomy by the name "sinuses" having been given to two perfectly different kinds of spaces connected with the skull. It may be as well, therefore, to state here at the outset, that the "sinuses" in the interior of the cranium which produce the grooves on the inner surface of the bones are venous channels along which the blood runs in its passage back from the brain, while the "sinuses" external to the cranial cavity (the frontal sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nostrils, and contain air.
lodges a process of the falx cerebri, and when open transmits a vein from the lining membrane of the nose to the superior longitudinal sinuses. On either side of the groove the bone is deeply concave, presenting depressions for the convolutions of the brain, and numerous small furrows for lodging the rami-

fications of the anterior branches of the middle meningeal arteries. Several small irregular fossæ are seen also on either side of the groove, for the reception of the Pacchionian bodies.

**Border.**—The border of the vertical portion is thick, strongly serrated, bevelled at the expense of the internal table above, where it rests upon the parietal bones, and at the expense of the external table at each side, where it receives the lateral pressure of those bones; this border is continued below into a triangular rough surface which articulates with the great wing of the sphenoid.

**Structure.**—The vertical portion and external angular processes are very thick, consisting of diploic tissue contained between two compact laminae.

**Horizontal or Orbital Portion of the Frontal Bone (Pars Orbitalis).**

This portion of the bone consists of two thin plates, the *orbital plates*, which form the vault of the orbit, separated from one another by a median gap, the ethmoidal notch.

**Surfaces.** **External Surface.**—The inferior or external surface of each orbital plate (*facies orbitalis*) consists of a smooth, concave, triangular lamina of bone, marked at its anterior and external part (immediately beneath the external angular process) by a shallow depression, the *lachrymal fossa* (*fossa glandulae lacrimalis*) for lodging the lachrymal gland; and at its anterior and internal part
by a depression (sometimes a small tubercle), the *trocklear fossa* (*fovea troclearis*), for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eye. The *ethmoidal notch* (*incisura ethmoidalis*) separates the two orbital plates; it is quadrilateral, and filled up, when the bones are united, by the cribiform plate of the ethmoid. The margins of this notch present several half-cells, which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the *ethmoidal cells*; two grooves are also seen crossing these edges transversely; they are converted into canals by articulation with the ethmoid, and are called the *anterior and posterior ethmoidal foramina or canals* (*foramen ethmoidale anterius* and *foramen ethmoidale posterius*): they open on the inner wall of the orbit. The anterior one transmits the nasal nerve and anterior ethmoidal vessels, the posterior one the posterior ethmoidal vessels. In front of the ethmoidal notch, on each side of the nasal spine, is the opening of the *frontal air sinus* (*sinus frontalis*). These are two irregular cavities, which extend upward and outward, a variable distance, between the two tables of the skull, and are separated from one another by a thin, bony septum (*septum sinus frontalis*), which is often displaced to one side. Within the sinuses imperfect trabeculae of bone often exist. The sinuses are beneath and give rise to the prominences above the supraorbital arches called the *superciliary ridges* (*areus superciliarii*). The frontal air sinuses are absent at birth, become apparent about the seventh year of life, and from this period until the age of twenty increase gradually in size. Sometimes, however, the sinuses remain very small or never develop at all—or one side may be large and the other small—or one may exist on one side and be absent on the other.  

The right sinus is usually the larger. These cavities are larger in men than in women. The floor of each sinus is very thin and is over the orbit and the upper border of the lateral mass of the ethmoid. The thinnest portion of the floor is at the upper and inner angle of the orbit, and at this point pus is apt to point in cases of empyema of the sinus. The frontal sinuses are lined by mucous membrane and each sinus communicates with the middle meatus of the nose by the infundibulum and part of the semilunar hiatus. In some cases the sinuses communicate with each other by means of an aperture in the septum and occasionally join the sinus in the crista galli of the ethmoid.  

**Internal Surface** (*cerebral surface, facies cerebralis*).—The internal surface of the horizontal portion presents the convex upper surfaces of the orbital plates, separated from each other in the middle line by the ethmoidal notch, and marked by eminences and depressions for the convolutions of the frontal lobes of the brain.  

**Border.**—The border of the horizontal portion is thin, serrated, and articulates with the lesser wing of the sphenoid.  

**Structure.**—The horizontal portion is thin, translucent, and composed entirely of compact tissue; hence the facility with which instruments can penetrate the cranium through this part of the orbit.  

**Development** (Fig. 45).—The frontal bone is formed in membrane, being developed by two centres, one for each lateral half, which make their appearance about the seventh or eighth week, above the orbital arches. From this point ossification extends, in a radiating manner, upward into the forehead and back-

---

2 Ibid.
ward over the orbit. At birth the bone consists of two pieces, which afterward become united, along the middle line, by a suture which runs from the vertex to the root of the nose. This suture usually becomes obliterated within a few years after birth; but it occasionally remains throughout life, constituting the metopic suture. Secondary centres of ossification appear for the nasal spine—one on either side of the internal angular process where it articulates with the lachrymal bone; and sometimes there is one on either side at the lower end of the coronal suture. This latter centre sometimes remains ununited, and is known as the pterion ossicle, or it may join with the parietal, sphenoid, or temporal bone.

**Articulations.**—With twelve bones: two parietal, the sphenoid, the ethmoid, two nasal, two superior maxillary, two lachrymal, and two malar.

**Attachment of Muscles.**—To three pairs: the Corrugator supercilii, Orbicularis palpebrarum, and Temporal, on each side.

### The Temporal Bone (Os Temporale).

The temporal ones (tempus, time) are paired bones, situated at the sides and base of the skull. Each presents for examination a squamous, mastoid, and petrous portion.

#### Squamous Portion of the Temporal Bone (Squama Temporalis).

The squamous portion (squama, a scale), the anterior and upper part of the bone, is scale-like in form, and thin and translucent in texture (Fig. 46).

![Fig. 46.—Right temporal bone, from without. (Spalteholz.)](image)

**Surfaces. Outer Surface (facies temporalis).**—Its outer surface is smooth, convex, and grooved at its back part for the middle or deep temporal artery (sulcus a. temporalis media); it affords attachment to the Temporal muscle and forms part of the temporal fossa. At its back part may be seen a curved ridge—part of the temporal ridge or line; it serves for the attachment of the temporal fascia and
limits the origin of the Temporal muscle. The boundary between the squamous and mastoid portions of the bone, as indicated by traces of the original suture, lies fully half an inch below this ridge. Projecting from the lower part of the squamous portion is a long, arched process of bone, the zygoma or zygomatic process (processus zygomaticus). This process is at first directed outward, its two surfaces looking upward and downward; it then appears as if twisted upon itself, and runs forward, its surfaces now looking inward and outward. The superior border of the process is long, thin, and sharp, and serves for the attachment of the temporal fascia. The inferior, short, thick, and arched, has attached to it some fibres of the Masseter muscle. Its outer surface is convex and subcutaneous; its inner is concave, and also affords attachment to the Masseter. The extremity, broad and deeply serrated, articulates with the malar bone. The zygomatic process is connected to the temporal bone by three divisions, called its roots—an anterior, middle, and posterior. The anterior, which is short, but broad and strong, is directed inward, to terminate in a rounded eminence, the eminencia articularis or articular eminence (tuberculum articulare) (Fig. 46). This eminence forms the front boundary of the glenoid or mandibular fossa (fossa mandibularis), and in the recent state is covered with cartilage. The middle root is known as the post-glenoid process or tubercle, and is very prominent in young bones. It separates the mandibular portion of the glenoid fossa from the external auditory meatus, and terminates at the commencement of a well-marked fissure, the Glaserian (petro-tympanic) fissure (fissura petro-tympanica [Glaseri]). The posterior root, which is strongly marked, runs from the upper border of the zygoma backward over the external auditory meatus. It is termed the supramastoid or temporal crest, and forms part of the lower temporal ridge. At the junction of the anterior root with the zygoma is a projection, called the tubercle, for the attachment of the external lateral ligament of the lower jaw; and between the anterior and middle roots is an oval depression, forming part of the glenoid (mandibular) fossa (γιζυνη, a socket), for the reception of the condyle of the lower jaw. This fossa is bounded, in front, by the eminentia articularis; behind, by the tympanic plate, which separates it from the external auditory meatus; it is divided into two parts by a narrow slit, the Glaserian or petro-tympanic fissure. The anterior or mandibular part, formed by the squamous portion of the bone, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the lower jaw. This part of the glenoid fossa presents posteriorly a small conical eminence, the post-glenoid process, already referred to. This process is the representative of a prominent tubercle which, in some of the mammals, descends behind the condyle of the jaw, and prevents it being displaced backward during mastication (Humphry). The posterior part of the glenoid fossa, which lodges a portion of the parotid gland, is formed chiefly by the tympanic plate, which constitutes the anterior wall of the tympanum and external auditory meatus. The plate of bone terminates above in the Glaserian fissure, and below forms a sharp edge, the vaginal process of the styloid (vagina processus styloidei), which gives origin to some of the fibres of the Tensor palati muscle. The Glasperian fissure, which leads into the tympanum, lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a separate canal, parallel to the Glasperian fissure, the canal of Huguier (canaliculus chordae tympani), on the outer side of the Eustachian tube, in the retiring angle between the squamous and petrous portions of the temporal bone.1 Between the posterior bony wall of the external auditory meatus

1 This small fissure must not be confounded with the large canal which lies above the Eustachian tube and transmits the Tensor tympani muscle.
and the posterior root of the zygoma is the area called the suprameatal triangle of Prof. Macewen. Through this space the surgeon pushes the gauge in order to carry it into the antrum of the mastoid process.

**Internal Surface (cerebral surface, facies cerebralis).**—The internal surface of the squamous portion (Fig. 47) is concave, presents numerous eminences and depressions for the convolutions of the cerebrum, and two well-marked grooves for the branches of the middle meningeal artery.

**Borders. Superior Border.**—The superior border, parietal margin (margo parietalis), is thin, bevelled at the expense of the internal surface, so as to overlap the lower border of the parietal bone, forming the *squamous suture.*

**Anterior Inferior Border.**—The anterior inferior border, sphenoidal margin (margo sphenoidalis), is thick, serrated, and bevelled, alternately at the expense of the inner and outer surfaces, for articulation with the great wing of the sphenoid.

**Posterior Inferior Border.**—The posterior inferior border, occipital margin (margo occipitalis), is serrated and articulates with the occipital bone.

**The Mastoid Portion of the Temporal Bone (Pars Mastoidea).**

The mastoid portion (*μαστός*, a nipple or teat) is situated at the posterior part of the bone (Figs. 46, 48, and 49).

**Surfaces. Outer Surface.**—The outer surface of the mastoid is rough, and gives attachment to the Occipito-frontalis and Retrahens aurem muscles. It is perforated by numerous foramina; one of these, of large size, situated at the posterior border of the bone, is termed the *mastoid foramen* (foramen mastoideum); it transmits a vein to the lateral sinus and a small artery from the occipital to supply the dura mater. The position and size of this foramen are very variable. It is not always present; sometimes it is situated in the occipital bone or in the suture between the temporal and the occipital. The mastoid portion is con-
continued below into a conical projection, the **mastoid process** (*processus mastoideus*), the size and form of which vary somewhat. The mastoid process begins to develop during the second year and does not attain full size until after puberty. This process serves for the attachment of the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid muscles. On the inner side of the mastoid process is a deep groove, the **digastric fossa** (*incisura mastoidea*), for the attachment of the Digastric muscle; and, running parallel with it, but more internal, the **occipital groove** (*sulcus a. occipitalis*), which lodges the occipital artery. The **suprameatal triangle** of Prof. Macewen is bounded by the posterior root of the zygoma, the posterior bony wall of the external auditory meatus, and an imaginary line joining these two. Through this triangle the surgeon enters his instrument in order to reach the mastoid antrum. Behind the suprameatal spine is a depression known as the **mastoid fossa** (*fossa mastoidea*), which contains numerous small openings for bloodvessels.

**Fig. 48.—Section through the petrous and mastoid portions of the temporal bone, showing the communication of the cavity of the tympanum with the mastoid antrum.**

**Internal Surface.**—The internal surface of the mastoid portion presents a deep, curved groove, the **sigmoid fossa** or **sulcus** (*sulcus sigmoideus*), which lodges part of the lateral sinus; and into it may be seen opening the mastoid foramen, which transmits an emissary vein from the lateral sinus to the posterior auricular or occipital vein and a small artery, the mastoid branch of the occipital artery (*ramus mastoideus*). The groove for the lateral sinus is separated from the innermost of the mastoid air-cells by only a thin lamina of bone, and even this may be partly deficient. A section of the mastoid process (Figs. 48 and 49) shows it to be hollowed out into a number of cellular spaces, communicating with each other, called the **mastoid cells** (*cellulae mastoidae*), which exhibit the greatest possible variety as to their size and number, and which do not exist at birth, but develop with the growth of the mastoid process. At the upper and front part of the bone these cells are large and irregular, and contain air. They diminish in size toward the lower part of the bone, those situated at the apex of the mastoid process being quite small and usually containing marrow. These **pneumatic cells** extend far beyond the mastoid. Some may reach the floor of the Eustachian
canal; others the jugular portion of the occipital bone; others the roof of the external auditory canal, and some pass up toward the squamous portion. Occasionally they are entirely absent, and the mastoid is solid throughout. In addition to these pneumatic cells may be seen a large, irregular cavity (Figs. 48 and 49), situated at the upper and front part of the section. It is called the mastoid or tympanic antrum (antrum tympanicum), and must be distinguished from the mastoid cells, though it communicates with them. The mastoid cells are not developed until after puberty, but the mastoid antrum is almost as large at birth as it is in the adult.

It is filled with air, and is lined with a prolongation of the mucous membrane of the tympanum, which extends into it through an opening, by which it communicates with the cavity of the tympanum. The mastoid antrum is bounded above by a thin plate of bone, the tegmen tympani, which separates it from the middle fossa of the base of the skull on the anterior surface of the petrous portion of the temporal bone; below by the mastoid process; externally by the squamous portion of the bone just below the supramastoid crest; and internally by the external semicircular canal of the internal ear, which projects into its cavity. The opening by which it communicates with the tympanum is situated at the superior internal angle of the posterior wall of that cavity; it is a triangular opening into that portion of the tympanic cavity which is known as the tympanic attic or epitympanic recess or space (aditus ad antrum)—that is to say, that portion of the tympanum which is above the level of the membrana tympani.

In consequence of the communication which exists between the tympanum and mastoid cells, inflammation of the lining membrane of the former cavity may easily travel backward to that of the antrum, leading to caries and necrosis of their walls and the risk of transference of the inflammation to the lateral sinus or encephalon.

1 Dr. D. Kerfoot Shute, in Reference Handbook of the Medical Sciences.
Borders. Superior Border.—The superior border of the mastoid portion is broad and rough, its serrated edge sloping outward, for articulation with the posterior inferior angle of the parietal bone.

Posterior Border.—The posterior border, also, uneven and serrated, articulates with the inferior border of the occipital bone between its lateral angle and jugular process.

The Petrous Portion of the Temporal Bone (Pars Petrosa [Pyramis]) (Fig. 47).

The petrous portion (πέτρα, a stone), so named from its extreme density and hardness, is a pyramidal process of bone wedged in at the base of the skull between the sphenoid and occipital bones. Its direction from without is inward, forward, and a little downward. It presents for examination a base, an apex, three surfaces, and three borders, and contains, in its interior, the essential parts of the organ of hearing.

Base.—The base is applied against the internal surface of the squamous and mastoid portions, its upper half being concealed; but its lower half is exposed by the divergence of those two portions of the bone, which brings into view the oval, expanded orifice of a canal leading into the tympanum, the meatus auditorius externus (meatus acusticus externus). The curved tympanic plate or part (pars tympanica) forms the anterior wall, the floor, and a part of the posterior wall of this meatus, while the squamous portion of the temporal completes it above and behind. The entrance to the meatus is bounded throughout the greater part of its circumference by the auditory process, which is the name applied to the free rough margin of the tympanic plate, and which gives attachment to the cartilaginous portion of the meatus. Superiorly the entrance to the meatus is limited by the posterior root of the zygoma. At the upper and posterior portion of the bony meatus is a spine of bone known as the suprameatal spine or spine of Henle (spina suprameatum), which is a valuable surgical landmark. In most skulls it is distinctly marked.

Apex (apex pyramidis).—The apex of the petrous portion, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal (foramen caroticum internum), and forms the posterior and external boundary of the foramen lacerum medium.

Surfaces. Anterior Surface (facies anterior pyramidis).—The anterior surface of the petrous portion (Fig. 47) forms the posterior part of the middle fossa of the skull. This surface is continuous with the squamous portion, to which it is united by a suture, the petro-squamous suture, the remains of which are distinct even at a late period of life. It presents six points for examination: (1) An eminence (eminentia arcuata) near the centre, which indicates the situation of the superior semicircular canal. (2) In front and a little to the outer side of this eminence a depression indicating the position of the tympanum; here the layer of bone which separates the tympanum from the cranial cavity is extremely thin, and is known as the tegmen tympani. (3) A shallow groove, sometimes double, leading outward and backward to an oblique opening, the hiatus Fallopii (hiatus canalis facialis), for the passage of the greater petrosal nerve and the petrosal branch of the middle meningeal artery. (4) A smaller opening (apertura superior canaliculi tympanici), occasionally seen external to the latter, for the passage of the smaller petrosal nerve. (5) Near the apex of the bone, the termination of the carotid canal, the internal carotid foramen (foramen caroticum internum), the wall of which in this situation is deficient in front. (6) Above the canal a shallow depression, the trigeminal depression (impressio trigemini), for the reception of the Gasserian ganglion.
Posterior Surface (facies posterior pyramidis).—The posterior surface forms the front part of the posterior fossa of the skull, and is continuous with the inner surface of the mastoid portion of the bone. It presents three points for examination: 1. About its centre, a large orifice, the meatus auditorius internus (meatus acusticus internus), whose size varies considerably; its margins are smooth and rounded, and it leads into a short canal, about four lines in length, which runs directly outward and is closed by a vertical plate, the lamina cribrosa, which is divided by a horizontal crest, the falciform crest (crista falciformis), into two unequal portions (Fig. 50). Each portion is subdivided by a little vertical crest into two parts, named, respectively, anterior and posterior. The lower portion presents three sets of foramina: one group just below the posterior part of the crest, the area cribrosa media, consisting of a number of small openings for the nerves to the saccule; below and posterior to this, the foramen singulare, or opening for the nerve to the posterior semicircular canal; in front and below the first, the tractus spiralis foraminosus, consisting of a number of small, spirally arranged openings which terminate in the canalis centralis cochleae and transmit the nerve to the cochlea; the upper portion, that above the crista, presents behind a series of small openings the area cribrosa superior, for the passage of filaments to the utricle and superior and external semicircular canal, and, in front, one large opening, the commencement of the aquaeductus Fallopii (canalis facialis), for the passage of the facial nerve. 2. Behind the meatus auditorius, a small slit (apertura externa aquaeductus vestibuli), almost hidden by a thin plate of bone, leading to a canal, the aquaeductus vestibuli, which transmits the ductus endolymphaticus together with a small artery and vein. In the interval between these two openings, but above them, is an angular depression (fossa subarcuata) which lodges a process of the dura mater, and transmits a small vein into the cancellous tissue of the bone. In the child this depression is represented by a large fossa, the flocular fossa, which extends backward as a blind tunnel under the superior semicircular canal.

Inferior Surface (facies inferior pyramidis).—The inferior or basilar surface (Fig. 51) is rough and irregular, and forms part of the base of the skull. Passing from the apex to the base, this surface presents eleven points for examination: 1. A rough surface, quadrilateral in form, which serves partly for the attachment of the Levator palati and Tensor tympani muscles. 2. The large, circular aperture of the carotid canal, the external carotid foramen (foramen caroticum externum); the canal ascends at first vertically, and then, making a bend, runs horizontally forward and inward; it transmits the internal carotid artery and the carotid plexus. Within the carotid canal are several openings (canaliculi caroticus tympanici) which transmit tympanic branches of the internal carotid artery and of the carotid plexus. 3. The opening of the aquaeductus cochleae (apertura externa canaliculi cochleae), a small triangular opening, lying on the inner side of the latter, close to the posterior border of the petrous portion; it transmits a vein from the cochlea, which joins the internal jugular. 4. Behind these openings a deep depression, the jugular fossa.

Fig. 50.—Diagrammatic view of the fundus of the internal auditory meatus: 1. Fallopect. 2. Anterior superior cribiform area. 2'. Internal opening of the aquaeductus Fallopii. 3. Vertical crest which separates the anterior and posterior superior cribiform areas. 4. Posterior superior cribiform area, with (4') openings for nerve-filaments. 5. Anterior inferior cribiform area. 5'. Spirally arranged, sieve-like openings for the nerves to the cochlea. 5'. Opening of the central canal of the cochlea. 6. Crest which separates the anterior and posterior inferior cribiform areas. 7. Posterior inferior cribiform area. 7'. Orifices for the branches of the nerve to the sacule. 8. Foramen singulare of Morgagni, with the anterior portion of the canal which gives passage to the nerve to the posterior semicircular canal. (Testut)
(fossa jugularis), which varies in depth and size in different skulls; it lodges the lateral sinus, and, with a similar depression on the margin of the jugular process of the occipital bone, forms the foramen lacerum posterius or jugular foramen. 5. A foramen which is the opening of a small canal (canaliculus tympanicus), for the passage of Jacobson’s nerve (the tympanic branch of the glossopharyngeal); this foramen is seen in front of the bony ridge dividing the carotid canal from the jugular fossa. 6. A small foramen on the wall of the jugular fossa, for the entrance of the auricular branch of the pneumogastric (Arnold’s) nerve. 7. Behind the jugular fossa a smooth, square-shaped facet, the jugular surface; it is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone. 8. The vaginal process (vagina processus styloidea), a very broad, sheath-like plate of bone, which extends backward from the carotid canal and gives attachment to part of the Tensor palati muscle; this plate divides behind into two laminae, the outer of which is continuous with the tympanic plate, the inner with the jugular process. 9. Between these laminae is the ninth point for examination, the styloid process (processus styloideus), a sharp spine, about an inch in length; it is directed downward, forward, and inward, varies in size and shape, and sometimes consists of several pieces united by cartilage; it affords attachment to three muscles, the Stylo-pharyngeus, Stylo-hyoides, and Stylo-glossus, and two ligaments, the stylo-hyoid and stylo-maxillary. 10. The stylo-mastoid foramen (foramen stylomastoidicum), a rather large orifice, placed between the styloid and mastoid processes; it is the termination of the aqueductus Fallopii, and transmits the facial nerve and stylo-mastoid artery. 11. The auricular fissure (fissura tympanomastoidea), situated between the tympanic plate and mastoid processes, for the exit of the auricular branch of the pneumogastric nerve.
THE TEMPORAL BONE

(Arnold's nerve). This fissure is the external opening of the canaliculus mastoideus, which passes to the aqueduct of Fallopian.

Borders. Superior Border (angulus superior pyramidis).—The superior, the longest, is grooved for the superior petrosal sinus, and has attached to it the tentorium cerebelli; at its inner extremity is a semilunar notch, upon which the fifth nerve lies.

Posterior Border (angulus posterior pyramidis).—The posterior border is intermediate in length between the superior and the anterior. Its inner half is marked by a groove, which, when completed by its articulation with the occipital, forms the channel for the inferior petrosal sinus. Its outer half presents a deep excavation, the jugular fossa (fossa jugularis), which, with a similar notch on the occipital, forms the foramen lacerum posterius. A projecting eminence of bone occasionally stands out from the centre of the notch, and divides the foramen into two parts.

Anterior Border (angulus anterior pyramidis).—The anterior border is divided into two parts—an outer, joined to the squamous portion by a suture, the remains of which are distinct; an inner, free, articulating with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions is seen the opening of the canalis musculotubarius. This canal is completely or partially divided into two canals, separated from one another by a thin plate of bone, the processus cochleariformis (septum canalis musculotubarius); they both lead into the tympanum, the upper one (semicanalis m. tensoris tympani) transmitting the Tensor tympani muscle, the lower one (semicanalis tubae auditivae) forming the bony part of the Eustachian tube or canal.

Structure.—The squamous portion is like that of the other cranial bones: the mastoid portion, cellular; and the petrous portion, dense and hard.

Development (Fig. 52).—The temporal bone is developed by ten centres, exclusive of those for the internal ear and the ossicula—viz., one of the squamous portion including the zygoma, one for the tympanic plate, six for the petrous and mastoid parts, and two for the styloid process. Just before the close of fetal life the temporal bone consists of four parts: 1. The squamo-zygomatic part, ossified in membrane from a single nucleus, which appears at its lower part about the second month. 2. The tympanic plate, an imperfect ring, in the concavity of which is a groove, the sulcus tympanicus, for the attachment of the circumference of the tympanic membrane. This is also ossified from a single centre, which appears about the third month. 3. The petro-mastoid part is developed from six centres, which appear about the fifth or sixth month. Four of these are for the petrous portion, and are placed around the labyrinth, and two for the mastoid (Vrolik). According to Huxley, the centres are more numerous, and are disposed so as to form three portions: (1) including most of the labyrinth, with a part of the petrous and mastoid, he has named prootic; (2) the rest of the petrous, the opisthotic; and (3) the remainder of the mastoid, the epiotic. The petromastoid is ossified in cartilage. 4. The styloid process is also ossified in cartilage from two centres: one for the base, which appears before birth, and is termed the
tympanohyal; the other, comprising the rest of the process, is named the stylohyal, and does not appear until after birth. Shortly before birth the tympanic plate joins with the squamous. The petrous and mastoid join with the squamous during the first year, and the tympanohyal portion of the styloid process about the same time. The stylohyal does not join the rest of the bone until after puberty, and in some skulls never becomes united. The subsequent changes in this bone are, that the tympanic plate extends outward and backward, so as to form the meatus auditorius. The extension of the tympanic plate, however, does not take place at an equal rate all around the circumference of the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the foramen of Huschke; this foramen may persist throughout life. The glenoid cavity is at first extremely shallow, and looks outward as well as downward; it becomes deeper and is ultimately directed downward. Its change in direction is accounted for as follows: the part of the squamous temporal which supports it lies at first below the level of the zygoma. As, however, the base of the skull increases in width, this lower part of the squama is directed horizontally inward to contribute to the middle fossa of the skull, and its surfaces therefore come to look upward and downward. The mastoid portion is at first quite flat, and the stylo-mastoid foramen and rudimentary styloid process lie immediately behind the entrance to the auditory meatus. With the development of the air-cells the outer part of the mastoid portion grows downward and forward to form the mastoid process, and the styloid process and stylo-mastoid foramen now come to lie on the under surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the aqueduct of Fallopius.

The downward and forward growth of the mastoid process also pushes forward the tympanic plate, so that the portion of it which formed the original floor of the meatus and containing the foramen of Huschke is ultimately found in the anterior wall. With the gradual increase in size of the petrous portion the flocular fossa or tunnel under the superior semicircular canal becomes filled up and almost obliterated.

Articulations.—With five bones—occipital, parietal, sphenoid, inferior maxillary, and malar.

Attachment of Muscles.—To fifteen: to the squamous portion, the Temporal; to the zygoma, the Masseter; to the mastoid portion, the Occipitofrontalis, Stero-mastoid, Splenius capitis, Trachelo-mastoid, Digastricus, and Retrahens aurum; to the styloid process, the Stylo-pharyngeus, Stylo-hyoides, and Stylo-glossus; and to the petrous portion, the Levator palati, Tensor tympani, Tensor palati, and Stapedius.

The Sphenoid Bone (Os Sphenoidale).

The sphenoid bone (αϕιδυ, a wedge) is situated at the anterior part of the base of the skull, articulating with all the other cranial bones, which it binds firmly and solidly together. In its form it somewhat resembles a bat with its wings extended; and is divided into a central portion or body, two greater and two lesser wings extending outward on each side of the body, and two processes—the pterygoid processes—which project from it below.

The Body of the Sphenoid Bone.

The body (corpus) is of large size and hollowed out in its interior so as to form a mere shell of bone. It presents for examination four surfaces—a superior, an inferior, an anterior, and a posterior.
Surfaces. Superior Surface (facies cerebralis) (Fig. 53).—In front is seen a prominent spine, the ethmoidal spine, for articulation with the cribiform plate of the ethmoid; behind this a smooth surface presenting, in the median line, a slight longitudinal eminence, with a depression on each side for lodging the olfactory lobes. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the optic groove (sulcus chiasmatis), behind which lies the optic chiasm; the groove is continuous on each side with the optic foramen (foramen opticum), for the passage of the optic nerve and ophthalmic artery. Behind the optic groove is a small eminence, olive-like in shape, the olfactory process or eminence (tuberculum sellae); and still more posteriorly, a deep depression, the pituitary fossa, or sella turcica (fossa hypophyseos), which lodges the circular sinus and the pituitary body (hypophysis). This fossa is perforated by numerous foramina, for the transmission of nutrient vessels into the substance of the bone. It is bounded in front by the olfactory eminence, and also by two small eminences, one on either side, called the middle clinoid processes (processus clinoidei medii) (zīvī, a bed), which are sometimes connected by a spiculum of bone to the anterior clinoid processes. It is bounded behind by a square-shaped plate of bone, the dorsum ephippii or dorsum sellae, terminating at each superior angle in a tubercle, the posterior clinoid process (processus clinoideus posterior). The size and form of these processes vary considerably in different individuals. They deepen the pituitary fossa, and serve for the attachment of prolongations from the tentorium cerebelli. The sides of the dorsum ephippii are notched for the passage of the sixth pair of nerves, and below present a sharp process, the petrosal process, which is joined to the apex of the petrous portion of the temporal bone, forming the inner boundary of the middle lacrateric foramen. Behind this plate the bone presents a shallow depression, which slopes obliquely backward, and is continuous with the basilar groove of the occipital bone; it is called the clivus, and supports the upper part of the pons Varolii. On either side of the body is a broad groove, curved something like the italic letter J; it lodges the internal carotid artery and the cavernous sinus, and is called the carotid or cavernous groove (sulcus caroticus). Along the outer margin of this groove, at its posterior part, is a ridge of bone in the angle between the body and greater wing, called the lingula (lingula sphenoidalis).

Posterior Surface.—The posterior surface, quadrilateral in form, is joined to the basilar process of the occipital bone. During childhood these bones are separated
by a layer of cartilage; but in after-life (between the eighteenth and twenty-fifth years) this becomes ossified, ossification commencing above and extending downward; and the two bones then form one piece.

**Anterior Surface.**—The anterior surface (Fig. 54) presents, in the middle line, a vertical ridge of bone, the ethmoidal or sphenoidal crest (crista sphenoidalis), which articulates in front with the perpendicular plate of the ethmoid, forming part of the septum of the nose. On either side of it are irregular openings leading into the sphenoidal cells or sinuses (sinus sphenoidales). These are two large, irregular cavities hollowed out of the interior of the body of the sphenoid bone, often extending into the pterygoid processes and base of the greater wings of the bone, and separated from one another by a more or less complete perpendicular bony septum (septum sinusum sphenoidaleum). Occasionally they extend into the basilar process of the occipital nearly as far as the foramen magnum. Their form and size vary considerably; they are seldom symmetrical, and are often partially subdivided by irregular, osseous laminae. One sinus or both sinuses may be absent. The septum is seldom quite vertical, being commonly bent to one or the other side. These sinuses do not exist in very young children, but appear, according to Laurent, in the seventh year, and, according to Tillaux, not until the twentieth year. After once appearing they increase in size as age advances. They are partially closed, in front and below, by two thin, curved plates of bone, the sphenoidal, spongy, or turbinated bones (conchae sphenoidales). At the upper part of each is a round opening (apertura sinus sphenoidalis) by which the sinus communicates with the upper and back part of the nose, and occasionally with the posterior ethmoidal cells or sinuses. The lateral margins of this surface present a serrated edge, which articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin, also rough and serrated, articulates with the orbital process of the palate bone, and the upper margin with the orbital plate of the frontal bone.

**Inferior Surface.**—The inferior surface presents, in the middle line, a triangular spine, the rostrum (rostrum sphenoidalis), which is continuous with the sphenoidal crest on the anterior surface, and is received into a deep fissure between the alae

---

1 In this figure, both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.
of the vomer. On each side may be seen a projecting lamina of bone, which runs horizontally inward from near the base of the pterygoid process: these plates, termed the vaginal processes, articulate with the edges of the vomer. Close to the root of the pterygoid process is a groove (sulcus pterygopalatinus), formed into a complete canal when articulated with the sphenoidal process of the palate bone; it is called the pterygo-palatine canal, and transmits the pterygo-palatine vessels and pharyngeal nerve.

The Greater or Temporal Wings of the Sphenoid Bone (Alæ Magnæ).

The greater wings are two strong processes of bone which arise from the sides of the body, and are curved in a direction upward, outward, and backward, each being prolonged behind into a sharp-pointed extremity, the alar or sphenoidal spine (spina angularis). Each wing presents three surfaces and a circumference.

Surfaces. Superior Surface (facies cerebralis).—The superior or cerebral surface (Fig. 53) forms part of the middle fossa of the skull; it is deeply concave, and presents eminences and depressions for the convolutions of the brain. At its anterior and internal part is seen a circular aperture, the foramen rotundum, for the transmission of the second division of the fifth nerve. Behind and external to this is a large, oval foramen, the foramen ovale, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve. At the inner side of the foramen ovale a small aperture may occasionally be seen opposite the root of the pterygoid process; it is the foramen Vessali, transmitting a small vein. Lastly, in the posterior angle, near to the spine of the sphenoid, is a short canal, sometimes double, the foramen spinosum; it transmits the middle meningeal artery.

External Surface.—The external surface (Fig. 54) is convex and divided by a transverse ridge, the pterygoid ridge or infratemporal crest (crista infratemporalis), into two portions. The superior or larger, convex from above downward, concave from before backward, enters into the formation of the temporal fossa, and gives attachment to part of the Temporal muscle. The inferior portion, smaller in size and concave, enters into the formation of the zygomatic fossa, and affords attachment to the External pterygoid muscle. It presents, at its posterior part, a sharp-pointed eminence of bone, the spine, to which are connected the internal lateral ligament of the lower jaw and the Tensor palati muscle. The pterygoid ridge, dividing the temporal and zygomatic portions, gives attachment to part of the External pterygoid muscle. At its inner and anterior extremity is a triangular spine of bone, which serves to increase the extent of origin of this muscle.

Anterior Surface (facies orbitalis).—The anterior or orbital surface, smooth and quadrilateral in form, assists in forming the outer wall of the orbit. It is bounded above by a serrated edge, for articulation with the frontal bone; below, by a rounded border which enters into the formation of the spheno-maxillary fissure. Internally, it presents a sharp border, which forms the lower boundary of the sphenoidal fissure, and has projecting from about its centre a little tubercle of bone, which gives origin to one head of the External rectus muscle of the eye; and at its upper part is a notch for the transmission of a recurrent branch of the lachrymal artery; externally it presents a serrated margin for articulation with the malar bone. One or two small foramina may occasionally be seen for the passage of branches of the deep temporal arteries; they are called the external orbital foramina.

Circumference (Fig. 53).—Commencing from behind, that portion of the circumference from the body of the sphenoid to the spine is serrated and articulates by its outer half with the petrous portion of the temporal bone, while the inner half forms the anterior boundary of the foramen lacerum medium, and presents

---

1 The small petrosal nerve sometimes passes through a special foramen between the foramen ovale and foramen spinosum.
the posterior aperture of the Vidian canal (canalis pterygoideus) for the passage of the Vidian nerve and artery. In front of the spine the circumference of the great wing presents a serrated edge, bevelled at the expense of the inner table below and of the external above, which articulates with the squamous portion of the temporal bone. At the tip of the great wing a triangular portion is seen, bevelled at the expense of the internal surface, for articulation with the anterior inferior angle of the parietal bone. Internal to this is a triangular, serrated surface, for articulation with the frontal bone; this surface is continuous internally with the sharp inner edge of the orbital plate, which assists in the formation of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

The Lesser or Orbital Wings of the Sphenoid Bone (Alæ Parvae).

The lesser wings (processes of Ingrassias) are two thin, triangular plates of bone which arise from the upper and lateral parts of the body of the sphenoid, and, projecting transversely outward, terminate in a sharp point (Fig. 53). The superior surface of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the brain. The inferior surface forms the back part of the roof of the orbit and the upper boundary of the sphenoidal fissure or foramen lacerum anterius (fissura orbitalis superior). This fissure is of a triangular form, and leads from the cavity of the cranium into the orbit; it is bounded internally by the body of the sphenoid—above, by the lesser wing; below, by the internal margin of the orbital surface of the great wing—and is converted into a foramen by the articulation of this bone with the frontal. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater and the ophthalmic vein. The anterior border of the lesser wing is serrated for articulation with the frontal bone; the posterior border, smooth and rounded, is received into the fissure of Sylvius of the brain. Each inner extremity of this border forms an anterior clinoid process (processus clinoideus anterior). The lesser wing is connected to the side of the body by two roots, the upper thin and flat, the lower thicker, obliquely directed, and presenting on its outer side, near its junction with the body, a small tubercle, for the attachment of the common tendon of origin of three of the muscles of the eye. Between the two roots is the optic foramen (foramen opticum), for the transmission of the optic nerve and ophthalmic artery.

The Pterygoid Processes of the Sphenoid Bone (Processus Pterygoidei).

The pterygoid processes (πτέρυγα, a wing; ειδός, likeness), one on each side, descend perpendicularly from the point where the body and greater wing unite (Fig. 55). Each process consists of an external and an internal lamina or plate, which are joined together by their anterior borders above, but are separated below, leaving an angular cleft, the pterygoid notch or fissure (fissura pterygoidea), in which the pterygoid process or tuberosity of the palate bone is received. The two plates diverge from each other from their line of connection in front, so as to form a V-shaped fossa, the pterygoid fossa (fossa pterygoidea). The external pterygoid plate (lamina lateralis processus pterygoidei) is broad and thin, turned a little outward, and, by its outer surface, forms part of the inner wall of the zygomatic fossa, giving attachment to the External pterygoid; its inner surface forms part of the pterygoid fossa, and gives attachment to the Internal pterygoid. The internal pterygoid plate (lamina medialis processus pterygoidei) is much narrower and longer, curving outward, at its extremity, into a hook-like process of bone, the hamular process.
(hamulus pterygoideus), around which turns the tendon of the Tensor palati muscle. The outer surface of this plate forms part of the pterygoid fossa, the inner surface forming the outer boundary of the posterior aperture of the nares. On the posterior surface of the base of the process, above the pterygoid fossa, is a small, oval, shallow depression, the scaphoid fossa (fossa scaphoidea), from which arises the Tensor palati, and above which is seen the posterior orifice of the Vidian canal (canalis pterygoideus [Vidii]). Below and to the inner side of the Vidian canal, on the posterior surface of the base of the internal plate, is a little prominence, which is known by the name of the pterygoid tubercle. The Superior constrictor of the pharynx is attached to the posterior edge of the internal plate. The anterior surface of the pterygoid process is very broad at its base, and forms the posterior wall of the sphenomaxillary fossa. It supports Meckel's ganglion. It presents, above, the anterior orifice of the Vidian canal; and below, a rough margin, which articulates with the perpendicular plate of the palate bone.

The Sphenoidal Spongy Bone.

The sphenoidal spongy, turbinal or turbinated bones (the bones of Bertin, concha sphenoidales) are two thin, curved plates of bones, which exist as separate pieces until puberty, and occasionally are not joined to the sphenoid in the adult. They are situated at the anterior and inferior part of the body of the sphenoid, an aperture (apertura sinus sphenoidalis) of variable size being left in the anterior wall of each, through which the sphenoidal sinuses open into the nasal fossae. They are irregular in form and taper to a point behind, being broader and thinner in front. Their upper surface, which looks toward the cavity of the sinus, is concave; their under surface convex. Each bone articulates in front with the ethmoid, externally with the palate; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side and the rostrum of the sphenoid on the inner.¹

Development.—Up to about the eighth month of foetal life the sphenoid bone consists of two distinct parts: a posterior or post-sphenoid part, which comprises the pituitary fossa, the greater wings, and the pterygoid processes; and an anterior or pre-sphenoid part, to which the anterior part of the body and lesser wings belong. It is developed by fourteen centres: eight for the posterior sphenoid division, and six for the anterior sphenoid. The eight centres for the posterior

¹ A small portion of the sphenoidal turbinated bone sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above.—Cleland, Roy. Soc. Trans., 1862.
sphenoid are: one for each greater wing and external pterygoid plate, one for each internal pterygoid plate, two for the posterior part of the body, and one on each side for the lingula. The six for the anterior sphenoid are: one for each lesser wing, two for the anterior part of the body, and one for each sphenoidal turbinated bone.

**Post-sphenoid Division.**—The first nuclei to appear are those for the greater wings (ali-sphenoids). They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates are also formed. Soon after, the nuclei for the posterior part of the body appear, one on either side of the sella turcica, and become blended together about the middle of fetal life. About the fourth month the remaining four centres appear, those for the internal pterygoid plates being ossified in membrane and becoming joined to the external pterygoid plate about the sixth month. The centres for the lingula speedily become joined to the rest of the bone.

**Pre-sphenoid Division.**—The first nuclei to appear are those for the lesser wings (orbito-sphenoids). They make their appearance about the ninth week, at the outer borders of the optic foramina. A second pair of nuclei appear on the inner side of the foramina shortly after, and, becoming united, form the front part of the body of the bone. The remaining two centres for the sphenoidal turbinated bones make their appearance about the fifth month. At birth they consist of small triangular laminae, and it is not till the third year that they become hollowed out and cone-shaped. About the fourth year they become fused with the lateral masses of the ethmoid, and hence, from an embryological point of view, may be regarded as belonging to the ethmoid.

The pre-sphenoid is united to the body of the post-sphenoid about the eighth month, so that at birth the bone consists of three pieces—viz., the body in the centre, and on each side the great wings with the pterygoid processes. The lesser wings become joined to the body at about the time of birth. At the first year after birth the greater wings and body are united. From the tenth to the twelfth year the spongy bones are partially united to the sphenoid, their junction being complete by the twentieth year. Lastly, the sphenoid joins the occipital from the eighteenth to the twenty-fifth year.

**Articulations.**—The sphenoid articulates with all the bones of the cranium, and five of the face—the two malar, the two palate, and vomer; the exact extent of articulation with each bone is shown in the accompanying figures.\(^1\)

**Attachment of Muscles.**—To eleven pairs: the Temporal, External pterygoid, Internal pterygoid, Superior constrictor, Tensor palatii, Levator palpebrarum, Obliquus oculi superior, Superior rectus, Internal rectus, Inferior rectus, External rectus.

**The Ethmoid Bone (Os Ethmoidale).**

The ethmoid (\[\text{\cyrillicop}\]), a sieve) is an exceedingly light, spongy bone, of a cubical form, situated at the anterior part of the base of the cranium, between the two orbits at the root of the nose, and contributing to form each of these cavities.

\(^1\) It also sometimes articulates with the tuberosity of the superior maxilla.
It consists of three parts: a horizontal plate, which forms part of the base of the cranium; a perpendicular plate, which forms part of the septum nasi; and two lateral masses of cells.

The **Horizontal Lamina** or **Cribriform Plate** (lamina cribrosa) (Fig. 57) forms part of the anterior fossa of the base of the skull, and is received into the ethmoid notch of the frontal bone between the two orbital plates. Projecting upward from the middle line of this plate is a thick, smooth, triangular process of bone, the **crista galli**, so called from its fancied resemblance to a cock's comb. Its base joins the cribriform plate. Its posterior border, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting alae (processus alares), which are received into corresponding depressions in the frontal, completing the foramen caecum behind. Its sides are smooth and sometimes bulging; in which case it is found to enclose a small sinus. On each side of the crista galli the cribriform plate is narrow and deeply grooved, to support the bulb of the olfactory tract, and is perforated by foramina for the passage of the olfactory nerves. These foramina are arranged in three rows: the innermost, which are the largest and least numerous, are lost in grooves on the upper part of the septum; the foramina of the outer row are continued on to the surface of the upper spongy bone. The foramina of the middle row are the smallest; they perforate the bone and transmit nerves to the roof of the nose. At the front part of the cribriform plate, on each

---

1 Sir George Humphry states that the crista galli is commonly inclined to one side, usually the opposite to that toward which the lower part of the perpendicular plate is bent.—The Human Skeleton, 1858, p. 277.
side of the crista galli, is a small fissure, which transmits the nasal branch of the ophthalmic nerve; and at its posterior part a triangular notch, which receives the ethmoidal spine of the sphenoid.

The **Vertical or Perpendicular Lamina or Plate** *(lamina perpendicularis or mesethmoid)* (Fig. 60) is a thin, flattened lamella of bone, which descends from the under surface of the cribiform plate, and assists in forming the septum of the nose. It is much thinner in the middle than at the circumference, and is generally deflected a little to one side. Its anterior border articulates with the nasal spine of the frontal bone and crest of the nasal bones. Its posterior border, divided into two parts, articulates by its upper half with the sphenoidal crest of the sphenoid, by its lower half with the vomer. The inferior border serves for the attachment of the triangular cartilage of the nose. On each side of the perpendicular plate numerous grooves and canals are seen, leading from the foramina on the cribiform plate; they lodge filaments of the olfactory nerves.

The **Lateral Mass or Labyrinth** *(labyrinthus ethmoidalis)* of the ethmoid consists of a number of thin-walled cellular cavities, the **ethmoidal cells** *(cellulae ethmoidales)* interposed between two vertical plates of bone, the outer one of which forms part of the orbit, and the inner one part of the nasal fossa of the corresponding side. There are two lateral masses, one on each side. The ethmoidal cells are not present at birth, but appear during the fifth year. In the disarticulated bone many of these cells appear to be broken; but when the bones are articulated they are closed in at every part, except where they open into the nasal fossae. The upper surface of each lateral mass presents a number of apparently half-broken cellular spaces; these are closed in, when articulated, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves on each side, converted into canals by articulation with the frontal; they are the **anterior and posterior ethmoidal canals** *(canalis ethmoidale anterius and posterius)*, and open on the inner wall of the orbit. The **posterior surface** also presents large, irregular cellular cavities, which are closed in by articulation with the sphenoidal turbinate bones and the orbital process of the palate. The cells at the anterior surface are completed by the lachrymal bone and nasal process of the superior maxillary, and those below also by the superior maxillary. The outer surface of each lateral mass is formed of a thin, smooth, oblong plate of bone, called the **os planum** *(lamina papyracea)*; it forms part of the inner wall of the orbit, and articulates, above, with the orbital plate of the frontal; below, with the superior maxillary; in front, with the lachrymal; and behind, with the sphenoid and orbital process of the palate.

From the **inferior part** of each lateral mass, immediately beneath the os planum, there projects downward and backward an irregular lamina of bone, called the **unciform process** *(processus uncinatus)*, from its hook-like form; it serves to close in the upper part of the orifice of the antrum, and articulates with the ethmoidal...
process of the inferior turbinated bone. It is often broken in disarticulating the bones.

The inner surface of each lateral mass forms part of the outer wall of the nasal fossa of the corresponding side. It is formed of a thin lamella of bone, which descends from the under surface of the cribiform plate, and terminates below in a free, convoluted margin, the middle turbinated or the inferior ethmoidal turbinate bone (concha nasalis media). The middle turbinated bone may contain a cell or cells, which are really ethmoidal cells. Howard A. Lothrop\(^1\) studied 1000 specimens, and found cells in 9 per cent. of them. He never found cells in children. As a rule, a turbinate cell communicates with a posterior ethmoidal cell, but may join an anterior ethmoidal cell. The cells may open into the superior meatus or into the middle meatus. The whole of this surface is rough and marked above by numerous grooves, which run nearly vertically downward from the cribiform plate; they lodge branches of the olfactory nerve, which are distributed on the mucous membrane covering the bone. The back part of this surface is subdivided by a narrow oblique fissure, the superior meatus of the nose (meatus nasi superior), bounded above by a thin, curved plate of bone, the superior turbinated bone (concha nasalis superior). By means of an orifice at the upper part of this fissure the posterior ethmoidal cells open into the nose. Below, and in front of the superior meatus, is seen the convex surface of the middle turbinated bone. It extends along the whole length of the inner surface of each lateral mass; its lower margin is free and thick, and its concavity, directed outward, assists in forming the middle meatus. It is by a large orifice at the upper and front part of the middle meatus that the anterior ethmoidal cells, and through them the frontal sinuses, communicate with the nose by means of a funnel-shaped canal, the infundibulum (infundibulum ethmoidale). The cellular cavities of each lateral mass, thus walled in by the os planum on the outer side and by the other bones already mentioned, are divided by a thin transverse bony partition into two sets, which do not communicate with each other; they are termed the anterior and posterior ethmoidal cells or sinuses. The former, more numerous, communicate with the frontal sinuses above and the middle meatus below by means of a long, flexuous canal, the infundibulum; the posterior, less numerous, open into the superior meatus and communicate (occasionally) with the sphenoidal sinuses. In some cases the ethmoidal sinuses communicate with the maxillary sinus. In some cases the os planum never develops, and the ethmoidal sinuses are separated from the orbit merely by membrane.

Development.—By three centres: one for the perpendicular lamella, and one for each lateral mass. The lateral masses are first developed, ossific granules making their appearance in the os planum between the fourth and fifth months of fetal life, and extending into the spongy bones. At birth the bone consists of the two lateral masses, which are small and ill-developed. During the first year after birth the perpendicular plate and crista galli begin to ossify, from a single nucleus, and become joined to the lateral masses about the beginning of the second year. The cribiform plate is ossified partly from the perpendicular plate and partly from the lateral masses. The formation of the ethmoidal cells, which completes the bone, does not commence until the end of the fourth year.

\(^1\) Annals of Surgery, May, 1903.
Articulations.—With fifteen bones: the sphenoid, two sphenoidal turbinated, the frontal, and eleven of the face—the two nasal, two superior maxillary, two lacrymal, two palatine, two inferior turbinated, and the vomer. No muscles are attached to this bone.

DEVELOPMENT OF THE CRANIUM.

The cerebral vesicles became enclosed by an envelope of membrane derived from the embryonic connective tissue about the head end of the chorda. This sac from the mesoderm is converted into fibrous tissue, and is known as the membranous cranium. In adult life the dura mater represents the membranous cranium.

In mammals the base and part of the sides of the membranous cranium become cartilaginous, but the roof and the remaining part of the sides remain membranous. Ossification commences in the roof and begins at a later period in the base. Although ossification begins in the membrane bones before it does in the cartilage bones, and the bones of the roof appear before the bones of the base and make considerable progress in their growth, at birth ossification is more advanced in the base, this portion of the skull forming a solid, immovable groundwork.

The Skull at Different Ages.—The skull at birth is relatively of large size as compared with the body. The cerebral cranium is large and the face is small. The fontanelles are open (see below). There are no sutures, but the margins of adjacent bones are widely separated by fibrous tissue which runs from the periosteum to the dura mater. The bones of the vault have no diploë and digital impressions are absent on the cranial surfaces. The parietal eminences and the frontal eminences are very distinct.¹

The orbits and parietal bones are large. If the base is examined it is noted that the mastoid processes are absent, that the lower border of the symphysis of the jaw is on a level with the condyles of the occipital bone, and that the pterygoid plates form "a large angle with the skull base, whereas in the adult the angle is almost a right one."² The lower jaw at birth is shown in Fig. 91.

The development of individual bones is considered under the appropriate headings. At puberty various pneumatic cells develop in bone and alter the form of the head and face.

After the eruption of the first set of teeth the age can be determined with reasonable certainty, and the degree of obliteration of the sutures will also give valuable information. In the vast majority of individuals the metopic suture becomes a mere trace during the fifth or sixth years. Ossification at the junction of the coronal and sagittal sutures and osseous union of the sphenoid and basilar portion of the occipital occur during maturity. The lower jaw of an adult is shown in Fig. 93.

In old age much of the diploë disappears and the bones become thinner and more porous. The alveolar surfaces of the jaws are absorbed if the teeth are lost, and the lower jaw alters its form (Fig. 91).

Sexual Differences.—It is not always possible to tell with certainty a woman's skull from a man's, but certain features are of value in reaching a conclusion. Virchow maintained that in non-European races it is very difficult to determine the sex from the skull, though among some savage races the differences may be great.³ It is always to be borne in mind that a woman's skull may be of the masculine type and a man's skull may be of the feminine type. There is no constant characteristic significant of the male or female skull. As a general rule, the female skull is smaller than the male; it is lighter, the muscular ridges and processes are less distinct, the mastoid processes are of less size, the orbital margins are thin and sharp (Cunningham), the forehead is more vertical and the vertex is more flattened (Cunningham), and the edge of the tympanic plate is "rounder and more tuberculous" (Cunningham). The frontal air sinuses are smaller in women than in men, one reason why the glabella is more prominent in men. The flattening of the vertex in women, previously referred to, causes the top of the head to be at a more marked angle with the forehead than in men (Ecker). This characteristic was recognized by the Greek sculptors (Havelock Ellis). The cephalic index, which shows the relation of skull breadth to skull length, is of doubtful value in determining sex.

The Fontanelles (Fonticuli).

Before birth the bones at the vertex and side of the skull are separated from each other by membranous intervals in which bone is deficient. These intervals are principally found at the four angles of the parietal bones. Hence there are six fontanelles. Their formation is due to the wave of ossification being circular and the bones quadrilateral; the ossific matter first meets at the margins of the bones, at the points nearest to their centres of ossification, and vacuities

¹ J. Bland Sutton in Henry Morris' Human Anatomy.
² Ibid.
³ Man and Woman, by Havelock Ellis.
or spaces are left at the angles, which are called **fontanelles**, so named from the pulsations of the brain, which are perceptible at the anterior fontanelle, were likened to the rising of water in a fountain. The **anterior or bregmatic fontanelle** (**fonticulus frontalís**) is the largest; it is lozenge-shaped, and corresponds to the junction of the sagittal and coronal sutures; the **posterior fontanelle** (**fonticulus occipitalís**), of smaller size, is triangular, and is situated at the junction of the sagittal and lambdoid sutures; the remaining ones, the **antero-lateral** and the **postero-lateral fontanelles** (**fonticulus sphenoidalís et fonticulus mastoídeus**), are situated at the inferior angles of each parietal bone. The latter are closed soon after birth; the two at the two superior angles remain open longer; the posterior being closed in a few months after birth; the anterior remaining open until the first or second year. These spaces are gradually filled in by an extension of the ossifying process or by the development of a Wormian bone. Sometimes the anterior fontanelle remains open beyond two years, and is occasionally persistent throughout life.

**Supernumerary, Wormian, Sutural or Epactal Bones (Ossa Triquetra).**

In addition to the constant centres of ossification of the skull, additional ones are occasionally found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and have been termed **Wormian bones** or **ossa triqueta**. They are most frequently found in the course of the lambdoid suture, but occasionally also occupy the situation of the fontanelles, especially the posterior and, more rarely, the anterior. Frequently one is found between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid, the **epicteric bone** or the **pterion ossicle** (Fig. 63). They have a great tendency to be symmetrical on the two sides of the skull, and they vary much in size, being in some cases not larger than a pin's head, and confined to the outer table; in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines, as described

---

1 Wormius, a physician of Copenhagen, is said to have given the first detailed description of these bones.
by Béclard and Ward. Their number is generally limited to two or three, but more than a hundred have been found in the skull of an adult hydrocephalic skeleton. In their development, structure, and mode of articulation they resemble the other cranial bones.

**Congenital Fissures and Gaps.**

An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins toward the centre of the bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

**BONES OF THE FACE (OSSA FACIEI).**

The Facial Bones are fourteen in number—viz., the
Two Nasal.
Two Superior Maxillae.
Two Lachrymal.
Two Malar.
Two Palate.
Two Inferior Turbinated.
Vomer.
Inferior Maxilla or Mandible.

"Of these, the upper and lower jaws are the fundamental bones for mastication, and the others are accessories; for the chief function of the facial bones is to provide an apparatus for mastication, while subsidiary functions are to provide for the sense organs (eye, nose, tongue) and a vestibule to the respiratory and vocal organs. Hence the variations in the shape of the face in man and the lower animals depend chiefly on the question of the character of their food and their mode of obtaining it."

**The Nasal Bones (Ossa Nasalia).**

The nasal (nasus, the nose) are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face, forming, by their junction, "the bridge" of the nose (Fig. 67). Each bone presents for examination two surfaces and four borders.

---

1 W. W. Keen, American edition, 1887, p. 185.
Surfaces. Outer Surface.—The outer surface is concave from above downward, convex from side to side; it is covered by the Pyramidalis and Compressor nasi muscles, and gives attachment at its upper part to a few fibres of the Occipito-frontalis muscle (Theile). It is marked by numerous small arterial furrows, and perforated about its centre by a foramen (foramen nasale), sometimes double, for the transmission of a small vein.

Inner Surface.—The inner surface is concave from side to side, convex from above downward; in which direction it is traversed by a longitudinal groove (sometimes a canal), for the passage of a branch of the nasal nerve.

Borders. Superior Border.—The superior border is narrow, thick, and serrated, for articulation with the nasal notch of the frontal bone.

Inferior Border.—The inferior border is broad, thin, sharp, inclined obliquely downward, outward, and backward, and serves for the attachment of the lateral cartilage of the nose. This border presents, about its middle, a notch, through which passes the branch of the nasal nerve above referred to, and is prolonged at its inner extremity into a sharp spine, which, when articulated with the opposite bone, forms the nasal angle.

External Border.—The external border is serrated, bevelled at the expense of the internal surface above and of the external below, to articulate with the nasal process of the superior maxillary.

Internal Border.—The internal border, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest, which forms part of the septum of the nose; this crest articulates above downward with the nasal spine of the frontal above, and the perpendicular plate of the ethmoid, and the triangular septal cartilage of the nose.

Development.—By one centre for each bone, which appears about the eighth week.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the superior maxillary.

Attachment of Muscles.—A few fibres of the Occipito-frontalis muscle.

The Superior Maxillary Bones (Upper Jaw Bones or Maxillæ).

The superior maxilla (maxilla, the jaw bone) are the most important bones of the face from a surgical point of view, on account of the number of diseases to which some of their parts are liable. Their careful examination becomes, therefore, a matter of considerable interest. They are the largest bones of the face, excepting the lower jaw, and form, by their union, the whole of the upper jaw. Each maxilla assists in the formation of three cavities, the roof of the mouth, the floor and outer wall of the nasal fossæ, and the floor of the orbit, and also enters into the formation of two fossæ, the zygomatic and sphenoid-maxillary, and two fissures, the sphenoid-maxillary and pterygo-maxillary. The bone presents for examination a body and four processes—malar, nasal, alveolar, and palate.

The Body of the Superior Maxilla (Corpus Maxillæ).

The body is somewhat cuboid and is hollowed out in its interior to form a large cavity, the antrum of Highmore (sinus maxillaris). Its surfaces are four—
an external or facial, a posterior or zygomatic, a superior or orbital, and an internal or nasal.

**Surfaces. External Surface (facies anterior).**—The external anterior or facial surface (Fig. 70) is directed forward and outward. It presents at its lower part a series of eminences corresponding to the position of the anterior five alveoli (juga alveolaria). Just above those for the incisor teeth is a depression, the *incisive* or *myriform fossa*, which gives origin to the Depressor alae nasi; and below it to the alveolar border is attached a slip of the Orbicularis oris. Above and a little external to it the Compressor nasi arises. More external is another depression, the *canine fossa* (*fossa canina*), larger and deeper than the incisive fossa, from which it is separated by a vertical ridge, the *canine eminence*, corresponding to the socket of the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the canine fossa is the *infraorbital foramen* (*foramen infraorbitale*), the termination of the infraorbital canal; it transmits the infraorbital vessels and nerve. Sometimes the infraorbital canal opens by two, very rarely by three, orifices on the face. Above the infraorbital foramen is the *margin of the orbit* (*margo infraorbitalis*), which affords partial attachment to the Levator labii superioris proprius. To the sharp margin of bone which bounds this surface in front and separates it from the internal surface is attached the Dilator naris posterior.

**Posterior Surface (facies infratemporalis).**—The posterior or zygomatic or *infra-temporal* surface is convex, directed backward and outward, and forms part of the zygomatic fossa. It is separated from the facial surface by a strong ridge of bone, the *malar process*, which extends upward from the socket of the second molar tooth. It presents about its centre several apertures leading to canals in the substance of the bone; they are termed the *posterior dental canals* (*foramina alveolaria*), and transmit the posterior dental vessels and nerves. At the lower part of this surface is a rounded eminence, the *maxillary tuberosity* (*tuber maxillare*), especially prominent after the growth of the wisdom-tooth, rough on its inner

---

**FIG. 70.—Left superior maxilla. Outer surface.**
side for articulation with the tuberosity of the palate bone, and sometimes with the external pterygoid plate. It gives attachment to a few fibres of origin of the Internal pterygoid muscle. Immediately above this is a smooth surface, which forms the anterior boundary of the sphenoid maxillary fossa; it presents a groove which, running obliquely downward, is converted into a canal by articulation with the palate bone, forming the posterior palatine or palato-maxillary canal for the descending palatine artery and great palatine nerve.

**Superior Surface (facies orbitalis).**—The superior or orbital surface is thin, smooth, triangular, and forms part of the floor of the orbit. It is bounded internally by an irregular margin which in front presents a notch, the lachrymal notch (incisura lacrimalis), which receives the lachrymal bone; in the middle articulates with the os planum of the ethmoid, and behind with the orbital process of the palate bone; bounded externally by a smooth, rounded edge which enters into the formation of the sphenoid maxillary fissure, and which sometimes articulates at its anterior extremity with the orbital plate of the sphenoid; bounded in front by part of the circumference of the orbit, which is continuous on the inner side with the nasal, on the outer side with the malar process. Along the middle line of the orbital surface is a deep groove, the infraorbital groove (sulcus infraorbitalis), for the passage of the infraorbital vessels and nerve. The groove commences at the middle of the outer border of this surface, and, passing forward, terminates in a canal, which subdivides into two branches. One of the canals, the infraorbital canal (canalis infraorbitalis), opens just below the margin of the orbit; the other, which is smaller, runs downward in the substance of the anterior wall of the antrum; it is called the anterior dental canal, and transmits the anterior dental vessels and nerve to the front teeth of the upper jaw. From the back part of the infraorbital canal a second small canal is sometimes given off, which runs downward in the outer wall of the antrum, and conveys the middle dental nerve to the bicuspide teeth. Occasionally this canal is derived from the anterior dental. At the inner and fore part of the orbital surface, just external to the lachrymal groove for the nasal duct, is a depression which gives origin to the Inferior oblique muscle of the eye.

**Internal Surface (facies nasalis).**—The internal or nasal surface (Fig. 71) is unequally divided into two parts by a horizontal projection of bone, the palate process (processus palatinus): the portion above the palate process forms part of the outer wall of the nasal fossae; that below it forms part of the cavity of the mouth. The superior division of this surface presents a large, irregular opening, the maxillary hiatus (hiatus maxillaris), leading into the antrum of Highmore. At the upper border of this aperture are numerous broken cellular cavities, which in the articulated skull are closed in by the ethmoid and lachrymal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal fossa, and behind it is a rough surface which articulates with the perpendicular plate of the palate bone, traversed by a groove which, commencing near the middle of the posterior border, runs obliquely downward and forward, and forms, when completed by its articulation with the palate bone, the posterior palatine or palato-maxillary canal. In front of the opening of the antrum is a deep groove, converted into a canal (canalis nasolacrimalis) by the lachrymal and inferior turbinated bones. The groove is called the lachrymal groove (sulcus lacrimalis), and lodges the nasal duct. More anteriorly is a well-marked rough ridge, the inferior turbinated crest (crista conchalis), for articulation with the inferior turbinated bone. The shallow concavity above this ridge forms part of the middle meatus of the nose, while that below it forms part of the inferior meatus. The portion of this surface below the palate process is concave, rough, and uneven, and perforated by numerous small foramina for the passage of nutrient vessels. It enters into the formation of the roof of the mouth.
The Antrum of Highmore, Maxillary Antrum, or Maxillary Sinus (sinus maxillaris), is a pyramidal cavity hollowed out of the body of the maxillary bone. It varies much in size. It is in most cases a large cavity, but in some is very small. The apex of the antrum, directed outward, is formed by the malar process; its base by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. The antral floor is, in most persons, on a level with the floor of the nasal fossa, but in some individuals it is on a lower level. Not unusually the inner wall of the antrum will be found to contain depressions or pockets. In rare instances an antral cavity is made into two by a bony septum. Its inner wall or base presents, in the disarticulated bone, a large, irregular aperture (hiatus maxillaris), which communicates with the nasal fossa. The margins of this aperture are thin and ragged, and the aperture itself is much contracted by its articulation with the ethmoid above, the inferior turbinated below, and the palate bone behind.  

In the articulated skull this cavity communicates with the middle meatus of the nasal cavity, generally by two small apertures left between the above-mentioned bones. In the recent state usually only one small opening exists, near the upper part of the cavity, sufficiently large to admit the end of a probe, the other being closed by the lining membrane of the sinus. That the opening into the nasal fossa does not afford the best drainage is demonstrated, when we note that it is at the highest and not at the lowest point of the antrum. "In rare instances the antrum communicates with the anterior ethmoidal cells, or the orbital and posterior ethmoidal cells and sphenoidal sinuses."  

At birth the antrum exists, though in a rudimentary state. It attains its full size from the twelfth to the fourteenth year.

Crossing the cavity of the antrum are often seen several projecting laminae of bone, similar to those seen in the sinuses of the cranium; and on its posterior wall

---

1 In some cases, at any rate, the lachrymal bone encroaches slightly on the anterior superior portion of the opening, and assists in forming the inner wall of the antrum.

2 D. Kerfoot Shute, in the Reference Handbook of the Medical Sciences.
are the posterior dental canals, transmitting the posterior dental vessels and nerves to the teeth. Projecting into the floor are several conical processes, corresponding to the roots of the first and second molar teeth; in some cases the floor is perforated by the teeth in this situation.

It is from the extreme thinness of the walls of this cavity that we are enabled to explain how a tumor growing from the antrum encroaches upon the adjacent parts, pushing up the floor of the orbit, and displacing the eyeball, projecting inward into the nose, protruding forward on to the cheek, and making its way backward into the zygomatic fossa and downward into the mouth.

The Processes of the Superior Maxillæ.

Malar Process (processus zygomaticus).—The malar process is a rough, triangular eminence, situated at the angle of separation of the facial from the zygomatic surface. In front it is concave, forming part of the facial surface; behind it is also concave, and forms part of the zygomatic fossa; above it is rough and serrated for articulation with the malar bone; whilst below a prominent ridge marks the division between the facial and zygomatic surfaces. A small part of the Masseter muscle arises from this process.

Nasal Process (processus frontalis).—The nasal process is a strong, triangular plate of bone, which projects upward, inward, and backward by the side of the nose, forming part of its lateral boundary. Its external surface is concave, smooth, perforated by numerous foramina, and gives attachment to the Levator labii superioris alaeque nasi, the Orbicularis palpebrarum, and Tendo oculi. Its internal surface forms part of the outer wall of the nasal fossa; at its upper part it presents a rough, uneven surface, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is a transverse ridge, the superior turbinate crest (crista ethmoidalis), for articulation with the middle turbinated bone of the ethmoid, bounded below by a shallow, smooth concavity which forms part of the middle meatus; below this again is the inferior turbinated crest (already described), where the process joins the body of the bone. Its upper border articulates with the frontal bone. The anterior border of the nasal process is thin, directed obliquely downward and forward, and presents a serrated edge for articulation with the nasal bone; its posterior border is thick, and hollowed into a groove, the lachrymal groove (sulcus lacrimalis), for the naso-lachrymal duct: of the two margins of this groove, the inner one articulates with the lachrymal bone; the outer one forms part of the circumference of the orbit. Just where the latter joins the orbital surface is a small tubercle, the lachrymal tubercle; this serves as a guide to the position of the lachrymal sac in the operation for fistula lachrymalis. The lachrymal groove in the articulated skull is converted into a canal (canalis lacrimalis) by the lachrymal bone and lachrymal process of the inferior turbinate; it is directed downward, and a little backward and outward, is about the diameter of a goose-quill, slightly narrower in the middle than at either extremity, and terminates below in the inferior meatus. It lodges the nasal duct.

Alveolar Process (processus alveolaris).—The alveolar process is the thickest and most spongy part of the bone, broader behind than in front, and excavated into deep cavities for the reception of the teeth (alveoli dentales). These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and subdivided into minor cavities by septa; those for the incisors are single, but deep and narrow. The limbus alveolaris is the broad inferior margin of the alveolar process. On the anterior surface are five projections correspond-
ing to the five anterior alveoli. They are called *juga alveolaria*. The cavities for the teeth are separated by *septa interalveolaria*. The Buccinator muscle arises from the outer surface of this process as far forward as the first molar tooth.

**Palate Process (processus palatinus).**—The palate process, thick and strong, projects horizontally inward from the inner surface of the bone. It is much thicker in front than behind, and forms a considerable part of the floor of the nostril and the roof of the mouth. Its *inferior surface* (Fig. 72) is concave, rough and uneven, contains numerous little cavities for the glands of the mucous membrane, and forms part of the roof of the mouth. This surface is perforated by numerous foramina for the passage of the nutrient vessels, channeled at the back part of its alveolar border by a longitudinal groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the great posterior palatine nerve from Meckel's ganglion, and presents little depressions for the lodgement of the palatine glands. When the two superior maxillary bones are articulated together, a large orifice may be seen in the middle line, immediately behind the incisor teeth. This is the *anterior palatine fossa* (*foramen incisivum*). On examining the bottom of this fossa four canals are seen: two branch off laterally to the right and left nasal fosse, and two, one in front and one behind, lie in the middle line. The former pair of these openings are named the *incisor foramina* or *foramina of Stenson*; they are the openings of the forking *incisor canal* (*canalis incisivus*), through which pass the anterior or terminal branches of the descending or posterior palatine arteries, which ascend from the mouth to the nasal fosse, and they contain the remains of Jacobson’s organ. The canals in the middle line are termed the *foramina of Scarpa*, and transmit the naso-palatine nerves, the left passing through the anterior, and the right through the posterior, canal. Occasionally in adults' skulls, often in children’s skulls, on the palatal surface of the process a delicate linear suture may sometimes be seen extending from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. This marks out the *inter-maxillary* or *pre-maxillary bones* or the *incisive bone* (*os incisivum*) on each side. It is the portion of the upper jaw which is in front of the anterior palatine foramen, and which in some animals exists permanently as a separate piece. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose, and the anterior nasal spine, and contains the sockets of the incisor teeth. The pre-maxillary bone has a separate centre of ossification and develops in association with the vertical plate of the ethmoid and the vomer. The incisive bones, which are always present in the foetus, usually join the rest of the bone.
early in development, more or less well-marked sutures (*sutura incisiva*) indicating the lines of union. In double hare-lip the incisive bones covered by the median part of the lip are frequently not joined to the palate processes of the superior maxillary bones, but are fixed to the nasal septum. Albrecht maintains that instead of two intermaxillary segments or incisive bones, each carrying two incisor teeth, there are originally four, each carrying the rudiment of one tooth and each of a triangular shape, the apices approaching at the anterior palatine canal. The segments are separated by five sutures. The maxilla is called the *exo-gnathion*, each mesial segment is called an *endo-gnathion*, and each lateral segment a *meso-gnathion*. In hare-lip the cleft may be purely in the soft parts, but may pass into the nostril, the alveolar portion of the maxilla, or through the palate bone (*cleft palate*). In hare-lip with cleft palate (*alveolar hare-lip*) Kölliker believes that the cleft is between the maxilla and the intermaxillary bone; that is, between the exo-gnathion and the meso-gnathion. Albrecht is of the opinion that the cleft is between the endo-gnathion and the meso-gnathion. In some cases of double hare-lip the pre-maxillary segment contains the germs of four incisors, and in such a case the cleft must be between the exo-gnathion and the meso-gnathion. In other cases it contains but two, and in such a case the cleft must be as indicated by Albrecht, as Fergusson's explanation is not in accordance with our knowledge of development. Fergusson believed that if the germs of four incisors are not present the missing ones were lost in the gap. The *upper surface* of the palate process is concave from side to side, smooth, and forms part of the floor of the nose. It presents the upper orifices of the foramina of

Stenson and Scarpa, the former being on each side of the middle line, the latter being situated in the intermaxillary suture, and therefore not visible unless the two bones are placed in apposition. The *outer border* of the palate process is incorporated with the rest of the bone. The *inner border* is thicker in front than behind, and is raised above into a ridge, the *nasal crest* (*crista nasalis*), which, with the corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. In front this crest rises to a considerable height, and this portion is named the *incisor crest*. The *anterior margin* is bounded by the thin, concave border of the opening of the nose, prolonged forward internally into a sharp process, forming, with a similar process of the opposite bone, the *anterior nasal spine* (*spina nasalis anterior*). The *posterior border* is serrated for articulation with the horizontal plate of the palate bone.

---

**Fig. 73.**—The pre-maxilla and its sutures. (Albrecht.)

**Fig. 74.**—Kölliker's theory of alveolar hare-lip. (Poirier and Charpy.)

**Fig. 75.**—Alveolar hare-lip according to the theory of Albrecht. (Poirier and Charpy.)
Development.—This bone commences to ossify at a very early period, and ossification proceeds in it with great rapidity, so that it is difficult to ascertain with certainty its precise number of centres. It appears, however, probable that it is ossified from four centres, which are deposited in membrane. 1. One which forms that portion of the body of the bone which lies internal to the infraorbital canal, including the floor of the orbit, the outer wall of the nasal fossa, and the nasal process. 2. A second which gives origin to that portion of the bone which lies external to the infraorbital canal and the malar process. 3. A third from which is developed the palatine process posterior to Stenson’s canal and the adjoining part of the nasal wall. 4. And a fourth for the front part of the alveolus which carries the incisor teeth and corresponds to the pre-maxillary bone of the lower animals. These centres appear about the eighth week, and by the tenth week the three first-named centres have become fused together and the bone consists of two portions, one the maxilla proper, and the other the pre-maxillary portion. The suture between these two portions on the palate persists till middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisive teeth is not formed by the pre-maxillary bone, but by an outgrowth from the facial part of the superior maxilla. The antrum appears as a shallow groove on the inner surface of the bone at an earlier period than any of the other nasal sinuses, its development commencing about the fourth month of foetal life. The sockets for the teeth are formed by the growing downward of two plates from the dental groove, which subsequently becomes divided by partitions jutting across from the one to the other. If the two palate processes fail to unite partially or completely, a partial or complete cleft palate results.

Articulations.—With nine bones: two of the cranium, the frontal and ethmoid, and seven of the face—viz., the nasal, malar, lachrymal, inferior turbinated, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate of the sphenoid, and sometimes with its external pterygoid plate.

Attachment of Muscles.—To twelve: the Orbicularis palpebrarum, Obliquus oculi inferior, Levator labii superioris alaeque nasi, Levator labii superioris proprius, Levator anguli oris, Compressor nasi, Depressor alae nasi, Dilatator naris posterior, Masseter, Buccinator, Internal pterygoid, and Orbicularis oris.

CHANGES PRODUCED IN THE UPPER JAW BY AGE.

At birth and during infancy the diameter of the bone is greater in an antero-posterior than in a vertical direction. Its nasal process is long, its orbital surface large, and its tuberosity well marked. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone approaches again in character to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

The Lachrymal Bone (Os Lacrimale).

The lachrymal (lachryma, a tear) is the smallest and most fragile bone of the face. There are two lachrymal bones. They are situated at the front part of the inner wall of the orbit (Fig. 67), and resemble somewhat in form, thinness,
and size a finger-nail; hence they are termed the **ossa unguis**. Each bone presents for examination two surfaces and four borders.

**Surfaces. External Surface.**—The external or **orbital** surface (Fig. 77) is divided by a vertical ridge, the **lachrymal crest** (*crista lacrimalis posterior*), into two parts. The portion of bone in front of this ridge, the **lachrymal sulcus** (*sulcus lacrimalis*), presents a smooth, concave, longitudinal groove, the free margin of which unites with the nasal process of the superior maxillary bone, completing the **lachrymal groove**. The upper part of this groove (* fossa sacri lacrimalis*) lodges the lachrymal sac; the lower part (*sulcus lacrimalis*) lodges the nasal duct. The portion of bone behind the ridge is smooth, slightly concave, and forms part of the inner wall of the orbit. The ridge, with a part of the orbital surface immediately behind it, affords attachment to the Tensor tarsi muscle: it terminates below in a small, hook-like projection, the **hamular process** (*hamulus lacrimalis*), which articulates with the lachrymal tubercle of the superior maxillary bone, and completes the upper orifice of the lachrymal groove. It sometimes exists as a separate piece, which is then called the **lesser lachrymal bone**.

**Internal Surface.**—The internal or **nasal** surface presents a depressed furrow, corresponding to the ridge on its outer surface. The surface of bone in front of this forms part of the middle meatus, and that behind it articulates with the ethmoid bone, filling in the anterior ethmoidal cells.

**Borders.**—Of the four borders, the **anterior** is the longest, and articulates with the nasal process of the superior maxillary bone. The **posterior**, thin and uneven, articulates with the os planum of the ethmoid. The **superior**, the shortest and thickest, articulates with the internal angular process of the frontal bone. The **inferior** is divided by the lower edge of the vertical crest into two parts; the posterior part articulates with the orbital plate of the superior maxillary bone; the anterior portion is prolonged downward into a pointed process, which articulates with the lachrymal process of the inferior turbinated bone and assists in the formation of the lachrymal groove.

**Development.**—By a single centre, which makes its appearance soon after ossification of the vertebrae has commenced.

**Articulations.**—With **four** bones: two of the cranium, the frontal and ethmoid, and two of the face, the superior maxillary and the inferior turbinated.

**Attachment of Muscles.**—To one muscle, the Tensor tarsi.

### The Malar Bone (Os Zygomaticum).

The name malar is derived from *mala*, the cheek. The malar or **yoke** bone is also called the **cheek bone**. There are two malar bones. Each is a small, quadrangular bone, situated at the upper and outer part of the face. They form the prominence of the cheek, part of the outer wall and floor of the orbit, and part of the temporal and zygomatic fossae (Fig. 78). Each bone presents for examination an external and an internal surface; four processes, the **frontal**, **orbital**, **maxillary**, and **zygomatic processes**; and four borders.

**Surfaces. External or Malar Surface (facies malaris).**—The external surface (Fig. 79) is smooth, convex, perforated near its centre by a small aperture, the **malar foramen** (*foramen zygomaticofaciale*), for the passage of nerves and vessels from the orbit. The malar surface is covered by the Orbicularis palpebrarum muscle, and affords attachment to the Zygomaticus major and minor muscles.
Internal or Temporal Surface (*facies temporalis*).—The internal surface (Fig. 80), directed backward and inward, is concave, presenting internally a rough, triangular surface, for articulation with the superior maxillary bone; and externally, a smooth concave surface, which above forms the anterior boundary of the temporal fossa, and below, where it is wider, forms part of the zygomatic fossa. This surface presents, a little above its centre, the aperture of a *malar canal* (*foramen zygomaticotemporale*), and affords attachment to a portion of the Masseter muscle at its lower part.

Processes. Frontal Process (*processus frontosphenoidalis*).—Of the four processes, the frontal is thick and serrated, and articulates with the external angular process of the frontal bone. To its orbital margin is attached the external tarsal ligament.

Orbital Process.—The orbital process is a thick and strong plate, which projects backward from the orbital margin of the bone. Its *supero-internal surface* (*facies
orbitalis), smooth and concave, forms, by its junction with the orbital surface of the superior maxillary bone and with the great wing of the sphenoid, part of the floor and outer wall of the orbit. Its infero-external surface, smooth and convex, forms part of the zygomatic and temporal fossae. Its anterior margin is smooth and rounded, forming part of the circumference of the orbit. Its posterior margin, rough and directed horizontally, articulates with the frontal bone behind the external angular process. Its posterior margin is rough and serrated for articulation with the sphenoid; internally it is also serrated for articulation with the orbital surface of the superior maxillary. At the angle of junction of the sphenoidal and maxillary portions a short, rounded, non-articular margin is generally seen; this forms the anterior boundary of the spheno-maxillary fissure: occasionally no such non-articular margin exists, the fissure being completed by the direct junction of the maxillary and sphenoid bones or by the interposition of a small Wormian bone in the angular interval between them. On the upper surface of the orbital process are seen a single or double temporo-malar foramen (foramen zygomaticoorbitale), the entrance of the temporo-malar canal. This canal may be bifurcated, or there may be two canals from the beginning; one of these usually opens on the posterior surface, the other (occasionally two) on the facial surface: they transmit filaments (temporo-malar) of the orbital branch of the superior maxillary nerve.

Maxillary Process.—The maxillary process is a rough, triangular surface which articulates with the malar process of the superior maxillary bone.

Zygomatic Process (processus temporalis).—The zygomatic process, long, narrow, and serrated, articulates with the zygomatic process of the temporal bone.

Borders.—Of the four borders, the antero-superior or orbital border is smooth, arched, and forms a considerable part of the circumference of the orbit. The antero-inferior or maxillary border is rough, and bevelled at the expense of its inner table, to articulate with the superior maxillary bone; affording attachment by its margin to the Levator labii superioris proprius, just at its point of junction with the superior maxillary. The postero-superior or temporal border, curved like an italic letter J, is continuous above with the commencement of the temporal ridge; below, with the upper border of the zygomatic arch: it affords attachment to the temporal fascia. The postero-inferior or zygomatic border is continuous with the lower border of the zygomatic arch, affording attachment by its rough edge to the Masseter muscle.

Development.—The malar bone ossifies generally from three centres, which appear about the eighth week—one for the zygomatic and two for the orbital portion—and fuse about the fifth month of foetal life. The bone is sometimes, after birth, seen to be divided by a horizontal suture into an upper and larger and a lower and smaller division. In some quadruped the malar bone consists of two parts, an orbital and a malar, which are ossified by separate centres.

Articulations.—With four bones: three of the cranium, frontal, sphenoid, and temporal; and one of the face, the superior maxillary.

Attachment of Muscles.—To four: the Levator labii superioris proprius, Zygomaticus major and minor, and Masseter.

The Palate Bone (Os Palatinum).

The palate bones (palatum, the palate) are situated at the back part of the nasal fossae: they are wedged in between the superior maxillary bones and the pterygoid processes of the sphenoid (Fig. 81). Each bone assists in the formation of three cavities: the floor and outer wall of the nose, the roof of the mouth, and the floor of the orbit, and enters into the formation of two fossae, the sphenomaxillary (fossa pterygopalatina) and pterygoid fossae (fossa pterygoidea); and one fissure, the sphenomaxillary fissure (fissura orbitalis inferior). In form the palate
bone somewhat resembles the letter L, and may be divided into an inferior or horizontal plate and a superior or vertical plate.

**The Horizontal Plate of the Palate Bone (Pars Horizontalis) (Fig. 83).**

The horizontal plate is of a quadrilateral form, and presents two surfaces and four borders.

**Surfaces.** Superior Surface (*facies nasalis*).—The superior or nasal surface, concave from side to side, forms the back part of the floor of the nasal cavity.

Inferior Surface (*facies palatina*).—The inferior or palatine surface, slightly concave and rough, forms the back part of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the Tensor palati muscle. At the outer extremity of this ridge is a deep groove, the *pterygopalatine groove* (*sulcus pterygopalatinus*), converted into a canal by its articulation with the tuberosity of the superior maxillary bone, and forming the lower end of the *posterior palatine canal* (*canalis pterygopalatinus*), the opening of which is called the *great palatine foramen* (*foramen palatinum majus*). Near this groove the orifices (*foramina palatinae minora*) of one or two small canals, *accessory posterior palatine canals* (*canales palatini*) may be seen. Through the posterior palatine canal emerge the descending palatine artery and the great posterior palatine nerve.

**Borders.**—The *anterior border* is serrated, bevelled at the expense of its inferior surface, and articulates with the palate process of the superior maxillary bone. The *posterior border* is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and, when united with the opposite bone, forms a projecting process, the *posterior nasal* or *palatine spine* (*spina nasalis posterior*), for the attachment of the Azygos uvula muscle. The *external border* is united with the lower part of the perpendicular plate almost at right angles. The *internal border*, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the opposite bone, forms a *crest* (*crista nasalis*) into which the vomer is received.
The Vertical or Perpendicular Plate of the Palate Bone (Pars Perpendicularis).

The vertical or perpendicular plate (Figs. 82 and 83) is thin, of an oblong form, and directed upward and a little inward. It presents two surfaces, an external and an internal, and four borders.

**Surfaces. Internal, Medial, or Nasal Surface** (facies nasalis).—The internal surface presents at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this is a well-marked horizontal ridge, the inferior turbinated crest (crista conchalis), for articulation with the inferior turbinated bone; above this, a second broad, shallow depression, which forms part of the middle meatus, surmounted above by a horizontal ridge less prominent than the inferior, the superior turbinated crest (crista ethmoidalis), for articulation with the middle turbinated bone. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the superior meatus.

**External, Lateral, or Maxillary Surface** (facies maxillaris).—The external surface is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the superior maxillary bone, its upper and back part being smooth where it enters into the formation of the spheno-maxillary fossa; it is also smooth in front, where it covers the orifice of the antrum. Toward the back part of this surface is a deep groove, the pterygo-palatine groove, converted into a canal, the posterior palatine canal, by its articulation with the superior maxillary bone. It transmits the posterior or descending palatine vessels and the great posterior palatine nerve from Meckel's ganglion.

**Borders.** Anterior Border (Fig. 82).—The anterior border is thin, irregular, and presents opposite the inferior turbinated crest a pointed, projecting lamina, the maxillary process (processus maxillaris), which is directed forward, and closes in the lower and back part of the opening of the antrum.

Posterior Border.—The posterior border (Fig. 83) presents a deep groove, the edges of which are serrated for articulation with the pterygoid process of the sphenoid. At the lower part of this border is seen a pyramidal process of bone, the pterygoid process or tuberosity of the palate (processus pyramidalis), which is received into the angular interval between the two pterygoid
plates of the sphenoid at their inferior extremity. This process presents at its back part a median groove and two lateral surfaces. The groove is smooth, and forms part of the pterygoid fossa, affording attachment to the Internal pterygoid muscle; whilst the lateral surfaces are rough and uneven, for articulation with the anterior border of each pterygoid plate. A few fibres of the Superior constrictor arise from the tuberosity of the palate bone. The base of this process, continuous with the horizontal portion of the bone, presents the aperture of the accessory descending palatine canals, through which pass the two smaller descending branches of Meckel's ganglion; whilst its outer surface is rough for articulation with the inner surface of the body of the superior maxillary bone.

**Superior Border.**—The superior border of the vertical plate presents two well-marked processes separated by an intervening notch or foramen. The anterior, or larger, is called the orbital process; the posterior, the sphenoidal process.

**Processes.** Orbital Process (processus orbitalis).—The orbital process, directed upward and outward, is placed on a higher level than the sphenoidal. It presents five surfaces, which enclose a hollow cellular cavity, and is connected with the perpendicular plate by a narrow, constricted neck. Of these five surfaces, three are articular, two non-articular or free surfaces. The three articular are the anterior or maxillary surface, which is directed forward, outward, and downward, is of an oblong form, and rough for articulation with the superior maxillary bone. The posterior or sphenoidal surface is directed backward, upward, and inward. It ordinarily presents a small, open cell, the orbital sinus (sinus orbitalis), which communicates with the sphenoidal cells, and the margins of which are serrated for articulation with the vertical part of the sphenoidal turbinate bone. "The orbital may communicate not only with the sphenoidal sinus and the ethmoidal cells, but, in rare instances, with the maxillary antrum." The internal or ethmoidal surface is directed inward, upward, and forward, and articulates with the lateral mass of the ethmoid bone. In some cases the cellular cavity opens on the internal surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates with both the posterior ethmoidal and the sphenoidal cells. The non-articular or free surfaces are the superior or orbital surface, directed upward and outward, of triangular form, concave, smooth, and forming the back part of the floor of the orbit; and the external or zygomatic surface, directed outward, backward, and downward, of an oblong form, smooth, lying in the spheno-maxillary fossa, and looking into the zygomatic fossa. The latter surface is separated from the orbital by a smooth, rounded border, which enters into the formation of the spheno-maxillary fissure.

Sphenoidal Process (processus sphenoidalis).—The sphenoidal process of the palate bone is a thin, compressed plate, much smaller than the orbital, and directed upward and inward. It presents three surfaces and two borders. The superior surface, the smallest of the three, articulates with the under surface of the sphenoidal turbinate bone; it presents a groove, which contributes to the formation of the pterygo-palatine canal. The internal surface is concave, and forms part of the outer wall of the nasal fossa. The external surface is divided into an articular and a non-articular portion: the former is rough, for articulation with the inner surface of the internal pterygoid plate of the sphenoid; the latter is smooth, and forms part of the spheno-maxillary fossa. The anterior border forms the posterior boundary of the sphenopalatine notch. The posterior border, serrated at the expense of the outer table, articulates with the inner surface of the internal pterygoid plate.

The orbital and sphenoidal processes are separated from one another by a deep notch, the sphenopalatine notch (incisura sphenopalatina), which is converted

---

1 Dr. D. Kerfoot Shute, in the Reference Handbook of the Medical Sciences.
into a foramen, the **sphenopaleine foramen** (foramen sphenopalatinum), by articulation with the under surface of the body of the sphenoid bone. Sometimes the two processes are united above, and form between them a complete foramen (Figs. 82 and 83), or the notch is crossed by one or more spicule of bone, so as to form two or more foramina. In the articulated skull this foramen is seen to pass from the sphen-maxillary fossa into the back part of the superior meatus. It transmits the sphenopaleine vessels and the superior nasal and naso-palatine nerves.

**Development.**—From a single centre, which makes its appearance about the second month at the angle of junction of the two plates of the bone. From this point ossification spreads inward to the horizontal plate, downward into the tuberosity, and upward into the vertical plate. In the fetus the horizontal plate is much larger than the vertical, and even after it is fully ossified the whole bone is at first remarkable for its shortness.

**Articulations.**—With six bones: the sphenoid, ethmoid, superior maxillary, inferior turbinated, vomer, and opposite palate.

**Attachment of Muscles.**—To four: the Tensor palati, Azygos uvulae, Internal pterygoid, and Superior constrictor of the pharynx.

**The Inferior Turbinated Bone** (Concha Nasalis Inferior).

The inferior turbinal or turbinated bones (turbo, a whirl) are situated one on each side of the outer wall of the nasal fossa. Each inferior turbinated bone (concha nasalis inferior) consists of a layer of thin, spongy bone, curled upon itself like a scroll—hence its name "turbinated"—and extends horizontally along the outer wall of the nasal fossa, immediately below the orifice of the antrum (Fig. 84). Each bone presents two surfaces, two borders, and two extremities.
Surfaces.—The *internasal surface* (Fig. 85) is convex, perforated by numerous apertures, and traversed by longitudinal grooves and canals for the lodgement of arteries and veins. In the recent state it is covered by the lining membrane of the nose. The *external surface* is concave (Fig. 86), and forms part of the inferior meatus.

Borders.—Its *upper border* is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions: of these, the anterior articulates with the inferior turbinated crest of the superior maxillary bone; the posterior with the inferior turbinated crest of the palate bone; the middle portion of the superior border presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the junction of the anterior fourth with the posterior three-fourths of the bone: it is small and pointed, and is called the *lachrymal process* (*processus lacrimalis*); it articulates by its apex with the anterior inferior angle of the lachrymal bone, and by its margins with the groove on the back of the nasal process of the superior maxillary, and thus assists in forming the canal for the nasal duct. At the junction of the two middle fourths of the bone, but encroaching on its posterior fourth, a broad, thin plate, the *ethmoidal process* (*processus ethmoidalis*), ascends to join the unciform process of the ethmoid; from the lower border of this process a thin lamina of bone curves downward and outward, hooking over the lower edge of the orifice of the antrum, which it narrows below: it is called the *maxillary process* (*processus maxillaris*), and fixes the bone firmly to the outer wall of the nasal fossa. The *inferior border* is free and thick, more especially in the middle of the bone. Bone extremities are more or less narrow and pointed, the posterior being the more tapering. If the bone is held so that its outer concave surface is directed backward (*i. e.*, toward the holder), and its superior border, from which the lachrymal and ethmoidal processes project, upward, the lachrymal process will be directed to the side to which the bone belongs.¹ In a study of 1000 specimens, Howard A. Lothrop² did not discover cells in the inferior turbinated bone.

Development.—By a single centre, which makes its appearance about the middle of foetal life.

Articulations.—With four bones: one of the cranium, the ethmoid, and three of the face, the superior maxillary, lachrymal, and palate.

No muscles are attached to this bone.

The Vomer (Ploughshare Bone).

The vomer (*vomer*, a ploughshare) is a single bone, situated vertically at the back part of the nasal fossae, forming part of the septum of the nose (Fig. 87). It is thin, somewhat like a ploughshare in form; but it varies in different individuals, being frequently bent to one or the other side; it presents for examination two surfaces and four borders.

¹ If the lachrymal process is broken off, as is often the case, the side to which the bone belongs may be known by recollecting that the maxillary process is nearer the back than the front of the bone.

² Annals of Surgery, May, 1903.
Surfaces.—The lateral surfaces are smooth, marked by small furrows for the lodgement of blood-vessels, and by a groove on each side, sometimes a canal, the naso-palatine groove or canal, which runs obliquely downward and forward to the intermaxillary suture; it transmits the naso-palatine nerve.

Borders.—The superior border, the thickest, presents a deep groove, bounded on each side by a horizontal projecting leaf of bone; these leaves are the alæ (alæ vomeris). The groove formed by the alæ receives the rostrum of the sphenoid, while the alæ are overlapped and retained by the vaginal processes, which project from the under surface of the body of the sphenoid at the base of the pterygoid processes. At the front of the groove a fissure is left for the transmission of blood-vessels to the substance of the bone. The inferior border, the longest, is broad and uneven in front, where it articulates with the two superior maxillary bones; thin and sharp behind, where it joins with the palate bones. The upper half of the anterior border usually consists of two laminae of bone, in the groove between which is received the perpendicular plate of the ethmoid; the lower half, also separated into two lamellae, receives between them the lower margin of the septal cartilage of the nose. The posterior border is free, concave, and separates the nasal fossae behind. It is thick and bifid above, thin below.

The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, with the intervention of very little, if any,
submucous connective tissue. Hence polypi are rarely found growing from this surface, though they frequently grow from the outer wall of the nasal fossae, where the submucous tissue is abundant.

**Development.**—The vomer at an early period consists of two laminae, separated by a very considerable interval, and enclosing between them a plate of cartilage, the **vomerine cartilage**, which is prolonged forward to form the remainder of the septum. Ossification commences in the membrane at the postero-inferior part of this cartilage by two centres, one on each side of the middle line, which extend to form the two laminae. They begin to coalesce at the lower part, but their union is not complete until after puberty.

**Articulations.**—With six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the superior maxillary and the two palate bones; and with the cartilage of the septum.

The vomer has no muscles attached to it.

**The Maxillary Bone, Inferior Maxilla, Mandible or Lower Jaw (Mandibula).**

The mandible, the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the **body**, and two perpendicular portions, the **rami**, which join the back part of the body nearly at right angles.

**The Horizontal Portion or Body of the Mandible (Corpus Mandibulae).**

The horizontal portion or body (Fig. 89) is convex in its general outline, and curved somewhat like a horseshoe. It presents for examination two surfaces and two borders.

**Surfaces. External Surface.**—The external surface is convex from side to side, concave from above downward. In the median line is a vertical ridge, the **symphysis**, which extends from the upper to the lower border of the bone, and indicates the point of junction of the two pieces of which the bone is composed at an early period of life. The lower part of the ridge terminates in a prominent triangular eminence, the **mental process** or **protuberance** (*protuberantia mentalis*). This eminence is rounded below, and often presents a median depression separating two processes, the **mental tubercles** (*tubera mentalia*). It forms the chin, a feature peculiar to the human skull. On either side of the symphysis, just below the
cavities for the incisor teeth, is a depression, the incisive or incisor fossa, for the attachment of the Levator menti (or Levator labii inferioris); more externally is attached a portion of the Orbicularis oris (accessorii orbicularis inferioris), and, still more externally, a foramen, the mental foramen (foramen mentale), for the passage of the mental vessels and nerve. This foramen is placed just below the interval between the two bicuspid teeth. Running outward from the base of the mental process on each side is a ridge, the external oblique line (linea obliqua). The ridge is at first nearly horizontal, but afterward inclines upward and backward, and is continuous with the anterior border of the ramus: it affords attachment to the Depressor labii inferioris and Depressor anguli oris; below it the Platysma myoides is attached.

Internal Surface.—The internal surface (Fig. 90) is concave from side to side, convex from above downward. In the middle line is an indistinct linear depres-

![Diagram of the mandible](https://example.com/diagram.png)
gland. The external oblique line and the internal or mylo-hyoidean line divide the body of the bone into a superior or alveolar and an inferior or basilar portion.

Borders.—The superior or alveolar portion of the body (pars alveolaris) has above a narrow border which is wider and the margins of which are thicker behind than in front. Its narrow margin is called the limbus alveolaris. It is hollowed into numerous cavities (alveoli dentales), for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. The cavities are separated from one another by septa interalveolaria. The juga alveolaria are prominences on the outer surface over the three front alveoli. To the outer side of the alveolar border the Buccinator muscle is attached upon the buccinator crest (crista buccinatoria) as far forward as the first molar tooth. The inferior or basilar portion (basis mandibulae) is rounded, longer than the superior, and thicker in front than behind; it presents a shallow groove, just where the body joins the ramus, over which the facial artery turns.

The Perpendicular Portions or Rami of the Mandible (Rami Mandibulae).

The perpendicular portions or rami are of a quadrilateral form. Each presents for examination two surfaces, four borders, and two processes.

Surfaces. External Surface.—The external surface is flat, marked with ridges, and gives attachment throughout nearly the whole of its extent to the Masseter muscle.

Internal Surface.—The internal surface presents about its centre an oblique foramen (foramen mandibulare) of the inferior dental canal (canalis mandibulae), for the passage of the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the lingula (lingula mandibulae), which gives attachment to the internal lateral ligament of the lower jaw, and at its lower and back part a notch leading to a groove, the mylo-hyoidian groove (sulcus mylohyoideus), which runs obliquely downward to the back part of the submaxillary fossa, and lodges the mylo-hyoid vessels and nerve. Behind the groove is a rough surface, for the insertion of the Internal pterygoid muscle. The inferior dental canal runs obliquely downward and forward in the substance of the ramus, and then horizontally forward in the body; it is here placed under the alveoli, with which it communicates by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward, to be lost in the cancellous tissue of the bone beneath the incisor teeth. This canal, in the posterior two-thirds of the bone, is situated nearer the internal surface of the jaw; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli.

Borders.—The lower border of the ramus is thick, straight, and continuous with the body of the bone. At its junction with the posterior border is the angle of the jaw (angulus mandibulae). The outer portion of the angle is called the gonion. The angle is either inverted or everted, and marked by rough, oblique ridges on each side, for the attachment of the Masseter externally, and the Internal pterygoid internally; the stylo-maxillary ligament is attached to the angle between these muscles. The anterior border is thin above, thicker below, and continuous with the external oblique line. The posterior border is thick, smooth, rounded, and covered by the parotid gland. The upper border of the ramus is thin, and presents two processes, separated by a deep concavity, the sigmoid notch (incisura mandibulae). Of these processes, the anterior is the coronoid, the posterior the condyloid.
Coronoid Process (processus coronoides).—The coronoid process is a thin, flattened, triangular eminence of bone, which varies in shape and size in different subjects, and serves chiefly for the attachment of the Temporal muscle. Its external surface is smooth, and affords attachment to the Temporal and Masseter muscles. Its internal surface gives attachment to the Temporal muscle and presents the commencement of a longitudinal ridge, which is continued to the posterior part of the alveolar process. On the outer side of this ridge is a deep groove, continued below on the outer side of the alveolar process; this ridge and part of the groove afford attachment, above, to the Temporal; below, to the Buccinator muscle.

Condyloid Process (processus condyloidens).—The condyloid process, shorter but thicker than the coronoid, consists of two portions: the condyle (capitulum mandibulae), and the constricted portion which supports the condyle, the neck (collum mandibulae). The condyle is of an oblong form, its long axis being transverse, and set obliquely on the neck in such a manner that its outer end is a little more forward and a little higher than its inner. It is convex from before backward and from side to side, the articular surface extending farther on the posterior than on the anterior aspect. At its outer extremity is a small tubercle for the attachment of the external lateral ligament of the temporomandibular joint. The neck of the condyle is flattened from before backward, and strengthened by ridges which descend from the fore part and sides of the condyle. Its lateral margins are narrow, the external one giving attachment to part of the external lateral ligament. Its posterior surface is convex; its anterior is hollowed out on its inner side by a depression, the pterygoid depression (fovea pterygoidea), for the attachment of the External pterygoid muscle.

The Sigmoid Notch (incisura mandibulae), separating the two processes, is a deep semilunar depression, crossed by the masseteric vessels and nerve.

Development.—The lower jaw is developed principally from membrane, but partly from cartilage. The process of ossification commences early—earlier than in any other bone except the clavicle. The greater part of the bone is formed from a centre of ossification (dentary), which appears between the fifth and sixth week in the membrane on the outer surface of Meckel’s cartilage. A second centre (splenial) appears in the membrane on the inner surface of the cartilage, and from this centre the inner wall of the sockets of the teeth is formed; this terminates above in the lingula. The anterior extremity of Meckel’s cartilage becomes ossified, forming the body of the bone on each side of the symphysis. Two supplemental patches of cartilage appear at the condyle and at the angle, in each of which a centre of ossification for these parts appears; the coronoid process is also ossified from a separate centre. At birth the bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

Articulation.—With the glenoid fossae of the two temporal bones.

Attachment of Muscles.—To fifteen pairs: to its external surface, commencing at the symphysis, and proceeding backward: Levator menti, Depressor labii inferioris, Depressor anguli oris, Platysma myoides, Buccinator, Masseter; a portion of the Orbicularis oris (Accessorii orbicularis inferioris) is also attached to this surface. To its internal surface, commencing at the same point: Genio-hyo-glossus, Genio-hyoideus, Mylo-hyoideus, Digastric, Superior constrictor, Temporal, Internal pterygoid, External pterygoid.

**CHANGES PRODUCED IN THE LOWER JAW BY AGE.**

The changes which the lower jaw undergoes after birth relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of the teeth in the aged, and the subsequent absorption of the alveoli; (2) to the size and situation of the dental canal; and (3) to the angle at which the ramus joins with the body.
SIDE VIEW OF THE LOWER JAW AT DIFFERENT PERIODS OF LIFE.

At birth (Fig. 91) the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175 degrees), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backward. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

After birth (Fig. 92) the two segments of the bone become joined at the symphysis, from below upward, in the first year; but a trace of separation may be visible in the beginning of the second year near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion, which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal after the second dentition is situated just above the level of the mylo-hyoid ridge, and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140 degrees.)

In the adult (Fig. 93) the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone,
and the dental canal runs nearly parallel with the mylo-hyoid line. The ramus is almost vertical in direction, and joins the body nearly at right angles.

In old age (Fig. 94) the bone becomes greatly reduced in size; for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains, consequently, the chief part of the bone is below the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The rami are oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backward.

The Sutures.

The bones of the cranium and face are connected to each other by means of sutures. That is, the articulating surfaces or edges of the bones are more or less roughened or uneven, and are closely adapted to each other, a small amount of intervening fibrous tissue, the sutural ligament, fastening them together. The cranial sutures may be divided into three sets: 1. Those at the vertex of the skull. 2. Those at the side of the skull. 3. Those at the base.

The sutures at the vertex of the skull are four: the metopic, the sagittal, the coronal, and the lambdoid.

The Metopic or Frontal Suture (sutura frontalis) is usually noted in adults as a trivial fissure, just above the glabella. At birth the two halves of the frontal bone are separated by the suture. This suture is, as a rule, almost completely or completely closed during the fifth or sixth year, but occasionally it remains intact (in about 8 per cent. of Europeans according to Prof. Cunningham).

The Interparietal or Sagittal Suture (sutura sagittalis) is formed by the junction of the two parietal bones, and extends from the middle of the frontal bone backward to the superior angle of the occipital. This suture is sometimes perforated, near its posterior extremity, by the parietal foramen; and in front, where it joins the coronal suture, a space is occasionally left which encloses a large Wormian bone.

The Fronto-parietal or Coronal Suture (sutura coronalis) extends transversely across the vertex of the skull, and connects the frontal with the parietal bones. It commences at the extremity of the greater wing of the sphenoid on one side, and terminates at the same point on the opposite side. The dentations of the suture are more marked at the sides than at the summit, and are so constructed that the frontal rests on the parietal above, whilst laterally the frontal supports the parietal.
The **Occipito-parietal** or **Lambdoid Suture** (*sutura lambdoidea*), so called from its resemblance to the Greek letter \( \Lambda \), connects the occipital with the parietal bones. It commences on each side at the mastoid portion of the temporal bone, and inclines upward to the end of the sagittal suture. The dentations of this suture are very deep and distinct, and are often interrupted by several Wormian bones.

The sutures at the side of the skull extend from the external angular process of the frontal bone to the lower end of the lambdoid suture behind. The **anterior portion** is formed between the lateral part of the frontal bone above and the malar and great wing of the sphenoid below, forming the **fronto-malar suture** (*sutura zygomatico-frontalis*) and **fronto-sphenoidal suture** (*sutura sphenofrontalis*). These sutures can also be seen in the orbit, and form part of the so-called **transverse facial suture**. The **posterior portion** is formed between the parietal bone above and the great wing of the sphenoid, the squamous and mastoid portions of the temporal bone below, forming the **spheno-parietal, squamo-parietal, and masto-parietal sutures**.

The **spheno-parietal** (*sutura sphenoparietalis*) is very short; it is formed by the tip of the great wing of the sphenoid, which overlaps the anterior inferior angle of the parietal bone.

The **squamo-parietal** or **squamous suture** (*sutura squamosa*) is arched. It is formed by the squamous portion of the temporal bone overlapping the middle division of the lower border of the parietal.

The **masto-parietal** (*sutura parietomastoidea*) is a short suture, deeply dentated, formed by the posterior inferior angle of the parietal and the superior border of the mastoid portion of the temporal.

The sutures at the base of the skull are the **basilar** in the centre, and on each side the **petro-occipital**, the **masto-occipital**, the **petro-sphenoidal**, and the **squamosphenoidal**.

The **Basilar Suture** (*fissura sphenoccipitalis*) is formed by the junction of the basilar surface of the occipital bone with the posterior surface of the body of the sphenoid. At an early period of life a thin plate of cartilage exists between these bones, but in the adult they become fused into one (*synchondrosis sphenoccipitalis*). Between the outer extremity of the basilar suture and the termination of the lambdoid an irregular suture exists, which is subdivided into two portions. The **inner portion**, formed by the union of the petrous part of the temporal with the occipital bone, is termed the **petro-occipital fissure** (*fissura petrooccipitalis*). The outer portion, formed by the junction of the mastoid part of the temporal with the occipital, is called the **masto-occipital suture** (*sutura occipitomastoidea*). Between the bones forming the petro-occipital suture a thin plate of cartilage exists; in the masto-occipital is occasionally found the opening of the mastoid foramen. Between the outer extremity of the basilar suture and the sphenoparietal an irregular suture may be seen, formed by the union of the sphenoid with the temporal bone. The inner and smaller portion of this suture is termed the **petro-sphenoidal fissure** (*fissura sphenopetrosa*); it is formed between the petrous portion of the temporal and the great wing of the sphenoid; the outer portion, of greater length and arched, is formed between the squamous portion of the temporal and the great wing of the sphenoid; it is called the **squamosphenoidal suture** (*sutura sphenosquamosa*).

The cranial bones are connected with those of the face, and the facial bones with each other, by numerous sutures, which, though distinctly marked, have received no special names. The only remaining suture deserving especial consideration is the **transverse suture**. This extends across the upper part of the face, and is formed by the junction of the frontal with the facial bones: it extends from the external angular process of one side to the same point on the opposite side, and connects the frontal with the malar, the sphenoid, the ethmoid, the lachrymal,
the superior maxillary, and the nasal bones on each side (sutura zygomatico-frontalis; the orbital portion of the sutura sphenofrontalis, sutura fronto-ethmoidalis, sutura frontolacrimalis, sutura frontomaxillaris, sutura nasofrontalis).

The sutures remain separate for a considerable period after the complete formation of the skull. It is probable that they serve the purpose of permitting the growth of the bones at their margins, while their peculiar formation, together with the interposition of the sutural ligament between the bones forming them, prevents the dispersion of blows or jars received upon the skull. Humphry remarks, "that, as a general rule, the sutures are first obliterated at the parts in which the ossification of the skull was last completed—viz., in the neighborhood of the fontanelles; and the cranial bones seem in this respect to observe a similar law to that which regulates the union of the epiphyses to the shafts of the long bones." The same author remarks that the time of their disappearance is extremely variable: they are sometimes found well marked in skulls edentulous with age, while in others which have only just reached maturity they can hardly be traced. The obliteration of the sutures takes place sooner on the inner than on the outer surface of the skull. The sagittal and coronal sutures are as a rule the first to become ossified—the process starting near the posterior extremity of the former and the lower ends of the latter.

THE SKULL AS A WHOLE.

The skull, formed by the union of the several cranial and facial bones already described, when considered as a whole is divisible into five regions: a superior region or vertex, an inferior region or base, two lateral regions, and an anterior region, the face.

The Vertex of the Skull.

The superior region, or vertex, presents two surfaces, an external and an internal.

Surfaces. External Surface. (This surface as seen from above is called the norma verticalis.)—The external surface is bounded, in front, by the glabella and supraorbital ridges; behind, by the occipital protuberance and superior curved lines of the occipital bone; laterally, by an imaginary line extending from the outer end of the superior curved line, along the temporal ridge, to the external angular process of the frontal bone. This surface includes the greater part of the vertical portion of the frontal, the greater part of the parietal, and the superior third of the occipital bone; it is smooth, convex, of an elongated oval form, crossed transversely by the coronal suture, and from before backward by the sagittal, which terminates behind in the lambdoid. The point of junction of the coronal and sagittal sutures is named the bregma, and is represented by a line drawn vertically upward from the external auditory meatus, the head being in its normal position. The point of junction of the sagittal and lambdoid sutures is called the lambda, and is about \( \frac{2}{3} \) inches above the external occipital protuberance. From before backward may be seen the frontal eminences and remains of the suture connecting the two lateral halves of the frontal bone; on each side of the sagittal suture are the parietal foramen and parietal eminence, and still more posteriorly the convex surface of the occipital bone. In the neighborhood of the parietal foramen the skull is often flattened, and the name of obellion is sometimes given to that point of the sagittal suture which lies exactly opposite to the parietal foramen.

Internal or Cerebral Surface.—The internal surface is concave, presents depressions for the convolutions of the cerebrum, and numerous furrows for the lodging of branches of the meningeal arteries. Along the middle line of this
surface is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind, where it lodges the superior longitudinal sinus, and by its margin affords attachment to the falx cerebri. On either side of it are several depressions for the Pacchionian bodies, and at its back part the internal openings of the parietal foramina. This surface is crossed, in front, by the coronal suture; from before backward by the sagittal; behind, by the lambdoid.

The Base of the Skull (the Skull being without the Mandible).

The inferior region, or base of the skull, presents two surfaces—an internal or cerebral, and an external or basilar.

Surfaces. Internal Upper or Cerebral Surface.—The internal or cerebral surface (Fig. 95) presents three fossae, called the anterior, middle, and posterior fossae of the cranium.

Anterior Fossa (fossa cranii anterior).—The anterior fossa is formed by the orbital plates of the frontal, the cribiform plate of the ethmoid, the anterior third of the superior surface of the body, and the upper surface of the lesser wings of the sphenoid bone. It is the most elevated of the three fossæ, convex externally where it corresponds to the roof of the orbit, concave in the median line in the situation of the cribiform plate of the ethmoid. It is traversed by three sutures, the ethmoo-frontal, ethmo-sphenoidal, and fronto-sphenoidal, and lodges the frontal lobe of the cerebrum. It presents, in the median line, from before backward, the commencement of the groove for the superior longitudinal sinus and the frontal crest for the attachment of the falx cerebri; the foramen cecum, an aperture formed between the frontal bone and the crista galli of the ethmoid, which, if pervious, transmits a small vein from the nose to the superior longitudinal sinus; behind the foramen cecum, the crista galli, the posterior margin of which affords attachment to the falx cerebri; on either side of the crista galli, the cribiform plate, which supports the olfactory bulb, and presents three rows of foramina for the transmission of its nervous filaments, and in front a slit-like opening for the nasal branch of the ophthalmic division of the fifth nerve. On the outer side of each olfactory groove are the internal openings of the anterior and posterior ethmoidal foramina; the former, situated about the middle of the outer margin of the olfactory groove, transmits the anterior ethmoidal vessels and the nasal nerve, which latter runs in a depression along the surface of the ethmoid to the slit-like opening above mentioned; while the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels. Farther back in the middle line is the ethmoidal spine, bounded behind by a slight elevation, separating two shallow longitudinal grooves which support the olfactory lobes. Behind this is a transverse sharp ridge, running outward on either side to the anterior margin of the optic foramen, and separating the anterior from the middle fossa of the base of the skull. The anterior fossa presents, laterally, depressions for the convolutions of the brain and grooves for the lodgement of the anterior meningeal arteries.

Middle Fossa (fossa cranii media).—The middle fossa, deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in front by the posterior margin of the lesser wing of the sphenoid, the anterior clinoid process, and the ridge forming the anterior margin of the optic groove; behind, by the superior border of the petrous portion of the temporal and the dorsum ephippii; externally by the squamous portion of the temporal anterior inferior angle of the parietal bone, and greater wing of the sphenoid. It is traversed by four sutures, the squamo-parietal, spheno-parietal, squamo-sphenoidal, and petro-sphenoidal. In the middle line, from before backward, is the optic
groove, behind which lies the optic commissure; the groove terminates on each side in the optic foramen, for the passage of the optic nerve and ophthalmic artery;
front by a small eminence on either side, the **middle clinoïd process**, and behind by a broad, square plate of bone, the **dorsum epiphílli**, surmounted at each superior angle by a tubercle, the **posterior clinoïd process**; beneath the latter process is a notch, for the sixth nerve. On each side of the sella turcica is the **cavernous groove**: it is broad, shallow, and curved somewhat like the italic letter f; it commences behind at the foramen lacerum medium, and terminates on the inner side of the anterior clinoïd process, and presents along its outer margin a ridge of bone. This groove lodges the cavernous sinus, the internal carotid artery, and the nerves of the orbit. The sides of the middle fossa are of considerable depth; they present depressions for the convolutions of the brain and grooves for the branches of the middle meningeal artery; the latter commence on the outer side of the foramen spinosum, and consist of two large branches, an anterior and a posterior; the former passing upward and forward to the anterior inferior angle of the parietal bone, the latter passing upward and backward. The following foramina may also be seen from before backward: Most anteriorly is the **foramen lacerum anterius**, or sphenoidal fissure (**fissura orbitalis superior**), formed above by the lesser wing of the sphenoid; below, by the greater wing; internally, by the body of the sphenoid; and sometimes completed externally by the orbital plate of the frontal bone. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the **foramen rotundum**, for the passage of the second division of the fifth or the superior maxillary nerve; still more posteriorly is seen a small orifice, the **foramen Vesalii**, an opening situated between the foramen rotundum and ovale, a little internal to both: it varies in size in different individuals, and is often absent; when present it transmits a small vein. It opens below into the pterygoid fossa, just at the outer side of the scaphoid depression. Behind and external to the latter opening is the **foramen ovale**, which transmits the third division of the fifth or the inferior maxillary nerve, the small meningeal artery, and the small petrosal nerve. On the outer side of the foramen ovale is the **foramen spinosum**, for the passage of the middle meningeal artery; and on the inner side of the foramen ovale is the **foramen lacerum medium**. The lower part of this aperture is filled with cartilage in the recent state. The Vidian nerve and a meningeal branch from the ascending pharyngeal artery pierce this cartilage. On the anterior surface of the petrous portion of the temporal bone is seen, from without inward, the eminence caused by the projection of the superior semicircular canal; in front of and a little outside this is a depression corresponding to the roof of the tympanum; the groove leading to the hiatus Fallopii, for the transmission of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the lesser petrosal nerve; and, near the apex of the bone, the depression for the Gasserian ganglion; and the internal orifice of the carotid canal (**foramen caroticum internum**), for the passage of the internal carotid artery and carotid plexus of nerves.

**Posterior Fossa (fossa cranii posterior).**—The posterior fossa, deeply concave, is the largest of the three, and situated on a lower level than either of the preceding. It is formed by the posterior third of the superior surface of the body of the sphenoid, by the occipital, the petrous and mastoid portions of the temporal, and the posterior inferior angle of the parietal bone; it is crossed by four sutures, the petro-occipital, the masto-occipital, the masto-parietal, and the basilar; and lodges the cerebellum, pons Varolii, and medulla oblongata. It is separated from the middle

---

1 See footnote, p. 95.
fossa in the median line by the dorsum ephippii, and on each side by the superior border of the petrous portion of the temporal bone. This border serves for the attachment of the tentorium cerebelli, is grooved for the superior petrosal sinus, and at its inner extremity presents a notch, upon which rests the fifth nerve. The circumference of the fossa is bounded posteriorly by the grooves for the lateral sinuses. In the centre of this fossa is the foramen magnum, bounded on either side by a rough tubercle, which gives attachment to the odontoid or check ligaments; and a little above these are seen the internal openings of the anterior condyloid foramina, through which pass the hypoglossal nerves and meningeal branches from the ascending pharyngeal arteries. In front of the foramen magnum is a grooved surface, formed by the basilar process of the occipital bone and by the posterior third of the superior surface of the body of the sphenoid, which supports the medulla oblongata and pons Varolii, and articulates on each side with the petrous portion of the temporal bone, forming the petro-occipital suture, the anterior half of which is grooved for the inferior petrosal sinus, the posterior half being encroached upon by the foramen lacerum posterius or jugular foramen (foramen jugulare). This foramen presents three compartments: through the anterior passes the inferior petrosal sinus; through the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and through the middle, the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. Above the jugular foramen is the internal auditory meatus, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the aqueductus vestibuli, which lodges the ductus endolympthicus; while between the two latter, and near the superior border of the petrous portion, is a small, triangular depression, the remains of the flocular fossa, which lodges a process of the dura mater and occasionally transmits a small vein into the substance of the bone. Behind the foramen magnum are the inferior occipital fossae, which lodge the hemispheres of the cerebellum, separated from one another by the internal occipital crest, which serves for the attachment of the falx cerebelli and lodges the occipital sinus. The posterior fossae are surmounted above by the deep transverse grooves for the lodgement of the lateral sinuses. These channels, in their passage outward, groove the occipital bone, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and terminate at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal bone the orifice of the mastoid foramen may be seen. Just previous to the termination of the groove the posterior condyloid foramen opens into it. Neither foramen is constant.

External Under or Basilar Surface (the view from below is called the norma basalis).—The external surface of the base of the skull (Fig. 96) is extremely irregular. It is bounded in front by the incisor teeth in the upper jaw; behind by the superior curved lines of the occipital bone; and laterally by the alveolar arch, the lower border of the malar bone, the zygoma, and an imaginary line extending from the zygoma to the mastoid process and extremity of the superior curved line of the occiput. It is formed by the palate processes of the superior maxillary and palate bones, the vomer, the pterygoid processes, under surface of the great wing, spinous processes and part of the body of the sphenoid, the under surface of the squamous, mastoid, and petrous portions of the temporal, and the under surface of the occipital bone. The anterior part of the base of the skull is raised above the level of the rest of this surface (when the skull is turned over for the purpose of examination), surrounded by the alveolar process, which is thicker behind than in front, and excavated by sixteen depressions for lodging the teeth of the upper jaw, the cavities varying in depth and size according to the teeth they contain. Immediately behind the incisor teeth is the anterior palatine fossa (foramen incisivum). At the bottom of this fossa may usually be seen four apertures:
two placed laterally, the foramina of Stenson, which open above, one in the floor of each nostril, and transmit the anterior branch of the posterior palatine vessels, and
two in the median line in the intermaxillary suture, the foramina of Scarps, one in front of the other, the anterior transmitting the left, and the posterior (the larger) the right, naso-palatine nerve. These two lateral canals are sometimes wanting, or they may join to form a single one, or one of them may open into one of the lateral canals above referred to. The palatine vault is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and crossed by a crucial suture, formed by the junction of the four bones of which it is composed. At the front part of this surface a delicate linear suture may frequently be seen, passing outward and forward from the anterior palatine fossa to the interval between the lateral incisor and canine teeth, and marking off the pre-maxillary portion of the bone. At each posterior angle of the hard palate is the posterior palatine foramen, for the transmission of the posterior palatine vessels and great descending palatine nerve; and running forward and inward from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the tuberosity of the palate bone, perforated by one or more accessory posterior palatine canals, and marked by the commencement of a ridge which runs transversely inward, and serves for the attachment of the tendinous expansion of the Tensor palati muscle. Projecting backward from the centre of the posterior border of the hard palate is the posterior nasal spine, for the attachment of the Azygos uvula muscle. Behind and above the hard palate is the posterior aperture of the nares, divided into two parts by the vomer, bounded above by the body of the sphenoid, below by the horizontal plate of the palate bone, and laterally by the internal pterygoid plate of the sphenoid. Each aperture measures about an inch in the vertical and about half an inch in the transverse direction. At the base of the vomer may be seen the expanded ale of this bone, receiving between them, on each side, the rostrum of the sphenoid. Near the lateral margins of the vomer, at the root of the pterygoid processes, are the pterygo-palatine canals. The pterygoid process, which bounds the posterior nares on each side, presents near its base the pterygoid or Vidian canal (canalis pterygoideus), for the Vidian nerve and artery. Each process consists of two plates, which bifurcate at the extremity to receive the tuberosity of the palate bone, and are separated behind by the pterygoid fossa, which lodges the Internal pterygoid muscle. The internal plate is long and narrow, presenting on the outer side of its base the scaphoid fossa, for the origin of the Tensor palati muscle, and at its extremity the hamular process, around which the tendon of this muscle turns. The external pterygoid plate is broad, forms the inner boundary of the zygomatic fossa, and affords attachment by its outer surface to the External pterygoid muscle.

Behind the nasal fossae in the middle line is the basilar surface of the occipital bone, presenting in its centre the pharyngeal spine, for the attachment of the Superior constrictor muscle of the pharynx, with depressions on each side for the insertion of the Rectus capitis anticus major and minor. At the base of the external pterygoid plate is the foramen ovale, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve; behind this, the foramen spinosum, which transmits the middle meningeal artery, and the prominent spinous process of the sphenoid, which gives attachment to the internal lateral ligament of the lower jaw and the Tensor palati muscle. External to the spinous process is the glenoid fossa, divided into two parts by the Glaserian fissure (page 84), the anterior portion concave, smooth, bounded in front by the eminentia articularis, and serving for the articulation of the condyle of the lower jaw; the posterior portion rough, bounded behind by the tympanic plate, and serving for the reception of part of the parotid gland. Emerging from between the laminae of the vaginal process of the tympanic plate is the styloid process, and at the base of this process is the stylo-mastoid foramen, for the exit of the facial nerve and entrance of the stylo-mastoid artery. External to the stylo-
mastoid foramen is the auricular fissure, for the auricular branch of the pneumogastric, bounded behind by the mastoid process. Upon the inner side of the mastoid process is a deep groove, the digastric fossa; and a little more internally the occipital groove, for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the foramen lacerum medium, bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and internally by the body of the sphenoid and basilar process of the occipital bone: it presents in front the posterior orifice of the Vidian canal; behind, the aperture of the carotid canal. The basilar surface of this opening is filled in the recent state by fibro-cartilaginous substance; across its upper or cerebral aspect passes the internal carotid artery. External to this aperture the petro-sphenoidal suture is observed, at the outer termination of which is seen the orifice of the canal for the Eustachian tube and that for the Tensor tympani muscle. Behind this suture is seen the under surface of the petrous portion of the temporal bone, presenting, from within outward, the quadrilateral, rough surface, part of which affords attachment to the Levator palati and Tensor tympani muscles; external to this surface the orifices of the carotid canal (foramen caroticum externum) and the aqueductus cochleae, the former transmitting the internal carotid artery and the ascending branches of the superior cervical ganglion of the sympathetic, the latter serving for the passage of a small artery and vein to the cochlea. Behind the carotid canal is a large aperture, the jugular foramen, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and is divided into three compartments by processes of dura mater. The anterior is for the passage of the inferior petrosal sinus; the posterior, for the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; the central one, for the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the ridge of bone dividing the carotid canal from the jugular foramen is the small foramen for the transmission of Jacobson’s nerve; and on the wall of the jugular foramen, near the root of the styloid process, is the small aperture for the transmission of Arnold’s nerve. Behind the basilar surface of the occipital bone is the foramen magnum, bounded on each side by the condyles, rough internally for the attachment of the check or odontoid ligaments, and presenting externally a rough surface, the jugular process, which serves for the attachment of the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament. On either side of each condyle anteriorly is the anterior condyloid fossa, perforated by the anterior condyloid foramen, for the passage of the hypoglossal nerve and often a meningeal branch of the ascending pharyngeal artery. Behind each condyle is the posterior condyloid fossa, perforated by the posterior condyloid foramen, for the transmission of a vein to the lateral sinus. Behind the foramen magnum is the external occipital protuberance, whilst on each side are seen the superior and inferior curved lines; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles, which are enumerated on page 76.

The Lateral Region of the Skull.

The view of the lateral region of the skull from the side is known as the norma lateralis. The lateral region is of a somewhat triangular form, the base of the triangle being formed by a line extending from the external angular process of the frontal bone along the temporal ridge backward to the outer extremity of the superior curved line of the occiput; and the sides by two lines, the one drawn downward and backward from the external angular process of the frontal bone to the angle of the lower jaw, the other from the angle of the jaw upward and back-
ward to the outer extremity of the superior curved line. This region is divisible into three portions—temporal fossa, mastoid portion, and zygomatic or infratemporal fossa.

The Temporal Fossa (fossa temporalis).—The temporal fossa is bounded above and behind by the temporal ridges, which extend from the external angular process of the frontal upward and backward across the frontal and parietal bones, curving downward behind to terminate in the posterior root of the zygomatic process, supra-

mastoid crest. In front it is bounded by the frontal, malar, and great wing of the sphenoid; externally by the zygomatic arch formed conjointly by the malar and temporal bones; below, it is separated from the zygomatic fossa by the pterygoid ridge, seen on the outer surface of the great wing of the sphenoid. This fossa is formed by five bones, part of the frontal, great wing of the sphenoid, parietal, squamous portion of the temporal and malar bones, and is traversed by six sutures, part of the transverse facial, spheno-malar, coronal, spheno-parietal, squamo-parietal, and squamo-sphenoidal. The point where the coronal suture crosses the superior temporal ridge is sometimes named the stephanion; and the region where the four bones, the parietal, the frontal, the squamous, and the greater wing of the sphenoid, meet, at the anterior inferior angle of the parietal bone, is named the pterion. This point is about on a level with the external angular process of the frontal bone and about one and a half inches behind it. This fossa is deeply concave in front, convex behind, traversed by grooves which lodge branches of the deep temporal arteries, and filled by the Temporal muscles.
The Mastoid Portion.—The mastoid portion of the side of the skull is bounded in front by the tubercle of the zygoma; above, by a line which runs from the posterior root of the zygoma to the end of the mastoid-parietal suture; behind and below by the masto-occipital suture. It is formed by the mastoid and part of the squamous and petrous portions of the temporal bone; its surface is convex and rough for the attachment of muscles, and presents, from behind forward, the mastoid foramen, the mastoid process, the external auditory meatus surrounded by the tympanic plate, and, most anteriorly, the temporo-maxillary articulation. The point where the posterior inferior angle of the parietal meets the occipital bone and mastoid portion of the temporal is named the asterion.

The Zygomatic or Infratemporal Fossa (*fossa infra-temporalis*).—The zygomatic fossa is an irregularly shaped cavity, situated below and on the inner side of the zygoma; bounded in front by the zygomatic surface of the superior maxillary bone and the ridge which descends from its malar process; behind, by the posterior border of the external pterygoid plate and the eminencia articularis; above, by the pterygoid ridge on the outer surface of the great wing of the sphenoid and the under part of the squamous portion of the temporal; below, by the alveolar border of the superior maxilla; internally, by the external pterygoid plate; and externally, by the zygomatic arch and ramus of the lower jaw (Fig. 98).

It contains the lower part of the Temporal, the External and Internal pterygoid muscles, the internal maxillary artery and vein, and inferior maxillary nerve and their branches. At its upper and inner part may be observed two fissures, the spheno-maxillary and pterygo-maxillary fissures.

The Spheno-maxillary Fissure (*fissura orbitalis inferior*), horizontal in direction, opens into the outer and back part of the orbit. It is formed above by the lower border of the orbital surface of the great wing of the sphenoid; below, by the external border of the orbital surface of the superior maxilla and a small part of the palate bone; externally, by a small part of the malar bone:1 internally, it joins at

---

1 Occasionally the superior maxillary bone and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from entering into its formation.
right angles with the pterygo-maxillary fissure. This fissure opens a communication from the orbit into three fossae—the temporal, zygomatic, and sphenomaxillary fossa; it transmits the superior maxillary nerve and its orbital branch, the infraorbital vessels, and ascending branches from the sphenopalatine or Meckel's ganglion.

The Pterygo-maxillary Fissure is vertical, and descends at right angles from the inner extremity of the preceding; it is a V-shaped interval, formed by the divergence of the superior maxillary bone from the pterygoid process of the sphenoid. It serves to connect the sphenomaxillary fossa with the zygomatic fossa, and transmits the internal maxillary artery.

The Sphenomaxillary or Pterygo-palatine Fossa (fossa pterygopalatina).—The sphenomaxillary fossa is a small, triangular space situated at the angle of junction of the sphenomaxillary and pterygo-maxillary fissures, and placed beneath the apex of the orbit. It is formed above by the under surface of the body of the sphenoid and by the orbital process of the palate bone; in front, by the superior maxillary bone; behind, by the anterior surface of the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoid; internally, by the vertical plate of the palate. This fossa has three fissures terminating in it—the sphenoidal, sphenomaxillary, and pterygo-maxillary; it communicates with the orbit by the sphenomaxillary fissure; with the nasal fossa by the sphenopalatine foramen, and with the zygomatic fossa by the pterygo-maxillary fissure. It also communicates with the cavity of the cranium, and has opening into it five foramina. Of these, there are three on the posterior wall: the foramen rotundum above; below and internal to this, the Vidian canal; and still more inferiorly and internally, the pterygo-palatine canal. On the inner wall is the sphenopalatine foramen, by which the sphenomaxillary communicates with the nasal fossa; and below is the superior orifice of the posterior palatine canal, besides occasionally the orifices of the accessory posterior palatine canals. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

The Anterior Region of the Skull.

The view of the anterior region of the skull from the front is known as the norma frontalis. It forms the face, is of an oval form, presents an irregular surface, and is excavated for the reception of two of the organs of sense, the eye and the nose. It is bounded above by the glabella and margins of the orbit; below, by the prominence of the chin; on each side by the malar bone and anterior margin of the ramus of the jaw. In the median line are seen from above downward the glabella, and diverging from it are the superciliary ridges, which indicate the situation of the frontal sinuses and supports the eyebrow. Beneath the glabella is the fronto-nasal suture, the mid-point of which is termed the nasion, and below this is the arch of the nose, formed by the nasal bones, and the nasal processes of the superior maxillary. The nasal arch is convex from side to side, concave from above downward, presenting in the median line the internasal suture (sutura internasalis), formed between the nasal bones, laterally the nasomaxillary suture (sutura nasomaxillaris), formed between the nasal bone and the nasal process of the superior maxillary bone. Below the nose is seen the opening of the anterior nares, which is heart-shaped, with the narrow end upward, and presents laterally the thin, sharp margins serving for the attachment of the lateral cartilages of the nose, and in the middle line below a prominent process, the anterior nasal spine, bounded by two deep notches. Below this is the internasal suture (sutura internasalis), and on each side of it the incisive fossa. Beneath this fossa are the alveolar processes of the upper and lower jaws, containing the incisor teeth, and at the lower part of the
median line the symphysis of the chin, the **mental process**, with its two mental tubercles, separated by a median groove, and the **incisive fossa** of the lower jaw.

On each side, proceeding from above downward, is the **supraorbital ridge**, terminating externally in the **external angular process** at its junction with the malar, and internally in the **internal angular process**; toward the inner third of this ridge is the **supraorbital notch** or **foramen**, for the passage of the supraorbital vessels and nerve. Beneath the supraorbital ridge is the opening of the orbit, bounded externally by the orbital ridge of the malar bone; below, by the orbital ridge formed by the malar and superior maxillary bones; internally, by the nasal process of the superior maxillary and the internal angular process of the frontal bone. On the outer side of the orbit is the quadrilateral anterior surface of the malar bone, perforated by one or two small malar foramina. Below the inferior margin of the orbit is the **infraorbital foramen**, the termination of the **infraorbital canal**, and beneath this the **canine fossa**, which gives attachment to the Levator anguli oris; still lower are the **alveolar processes**, containing the teeth of the upper and lower jaws. Beneath the alveolar arch of the lower jaw is the **mental foramen**, for the passage of the mental vessels and nerve, the **external oblique line**, and at the lower border of the bone, at the point of junction of the body with the ramus, a shallow groove for the passage of the facial artery.

**Orbits, Orbital Cavities, or Orbital Fossae.**—The orbits (from *orbis*, a circle) (Fig. 99) are two quadrilateral pyramidal cavities, situated at the upper and anterior
part of the face, their bases being directed forward and outward, and their apices backward and inward, so that the axes of the two, if continued backward, would meet over the body of the sphenoid bone. The wide orbital opening or mouth is called the aditus orbitae. The orbit is lined with periosteum, the periorbita. Each orbit (orbita) is formed of seven bones, the frontal, sphenoid, ethmoid, superior maxillary, malar, lachrymal, and palate; but three of these, the frontal, ethmoid, and sphenoid, enter into the formation of both orbits, so that the two cavities are formed of eleven bones only. Each cavity presents for examination a roof, a floor, an inner and an outer wall, four angles, a circumference or base, and an apex.

The Roof (paries superior).—The roof is concave, directed downward and slightly forward, and formed in front by the orbital plate of the frontal; behind, by the lesser wing of the sphenoid. This surface presents internally the depression for the cartilaginous pulley of the Superior oblique muscle; externally, the depression for the lachrymal gland; and posteriorly, the suture connecting the frontal and lesser wing of the sphenoid.

The Floor (paries inferior).—The floor is directed upward and outward, and is of less extent than the roof; it is formed chiefly by the orbital process of the superior maxillary; in front, to a small extent, by the orbital process of the malar, and behind, by the superior surface of the orbital process of the palate. This surface presents at its anterior and internal part, just external to the lachrymal groove, a depression for the attachment of the Inferior oblique muscle; externally, the suture between the malar and superior maxillary bones; near its middle, the infra-orbital groove; and posteriorly, the suture between the maxillary and palate bones.

Inner or Medial Wall (paries medialis).—The inner wall is flattened, nearly vertical, and formed from before backward by the nasal process of the superior maxillary, the lachrymal, os planum of the ethmoid, and a small part of the body of the sphenoid. This surface presents the lachrymal groove and crests of the lachrymal bone, and the sutures connecting the lachrymal with the superior maxillary, the ethmoid with the lachrymal in front, and the ethmoid with the sphenoid behind.

Outer or Lateral Wall (paries lateralis).—The outer wall is directed forward and inward, and is formed in front by the orbital process of the malar bone; behind, by the orbital surface of the greater wing of the sphenoid. On it are seen the orifices of one or two malar canals, and the suture connecting the sphenoid and malar bones.

Angles.—The superior external angle is formed by the junction of the upper and outer walls; it presents from before backward, the suture connecting the frontal with the malar in front and with the great wing of the sphenoid behind; quite posteriorly is the foramen lacerum anterius, or sphenoidal fissure, which transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The superior internal angle is formed by the junction of the upper and inner wall, and presents the suture connecting the frontal bone with the lachrymal in front and with the ethmoid behind. The point of junction of the anterior border of the lachrymal with the frontal has been named the dacyron. This angle presents two foramina, the anterior and posterior ethmoidal foramina, the former transmitting the anterior ethmoidal vessels and nasal nerve, the latter the posterior ethmoidal vessels. The inferior external angle, formed by the junction of the outer wall and floor, presents the sphen-o-maxillary fissure, which transmits the superior maxillary nerve and its orbital branches, the infraorbital vessels, and the ascending branches from the sphenopalatine or Meckel's ganglion. The inferior internal angle is formed by the union of the lachrymal bone and the os planum of the ethmoid with the superior maxillary and palate bones.
Circumference.—The circumference or base of the orbit, quadrilateral in form, is bounded above (margo supraorbitalis) by the supraorbital ridge; below (margo infraorbitalis), by the anterior border of the orbital plate of the malar and superior maxillary bones; externally, by the external angular process of the frontal and malar bones; internally, by the internal angular process of the frontal and the nasal process of the superior maxillary. The circumference is marked by three sutures, the fronto-maxillary internally, the fronto-malar externally, and the malar-maxillary below; it contributes to the formation of the lacrimal groove, and presents, above, the supraorbital notch (or foramen), for the passage of the supraorbital vessels and nerve.

Apex.—The apex, situated at the back of the orbit, corresponds to the optic foramen, a short circular canal which transmits the optic nerve and ophthalmic artery. It will thus be seen that there are nine openings communicating with each orbit—viz., the optic foramen, sphenoidal fissure, sphenomaxillary fissure, supraorbital foramen, infraorbital canal, anterior and posterior ethmoidal foramina, malar foramina, and the canal for the nasal duct.

The Nasal Cavity (cavum nasi).—The nasal cavities or nasal fossae (Figs. 84 and 100) are two large, irregular cavities situated on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum, the septum of the nose (septum nasi osseum), formed by the perpendicular plate of the ethmoid and by the vomer. Each cavity communicates by a large aperture, the anterior nasal aperture (apertura pyriformis), with the front of the face, and by the two posterior nares (echoanae) with the naso-pharynx behind. These fossae are much

---

1 Quain, Testut, and others give the apex of the orbit as corresponding with the inner end of the sphenoidal fissure. It seems better, however, to adopt the statement in the text, since the muscles of the eyeball take origin around the optic foramen, and diverge from it to the globe of the eye.

2 In the skull freed of soft parts, the anterior nasal cavities open in front by the apertura pyriformis. In the skull with the soft parts in place they open by the anterior nares.
narrower above than below, and in the middle than at the anterior or posterior openings; their depth, which is considerable, is much greater in the middle than at either extremity. "The nasal fossae are surrounded by four other fossae—above is the cranial fossa; laterally, the orbital fossa; and below, the cavity of the mouth." Each nasal fossa communicates with four sinuses, the frontal above, the sphenoidal behind, and the maxillary and ethmoidal on the outer wall. Each fossa also communicates with four cavities: with the orbit by the lacrimal groove, with the mouth by the anterior palatine canal, with the cranium by the olfactory foramina, and with the sphen-maxillary fossa by the sphenopalatine foramen; and they occasionally communicate with each other by an aperture in the septum. The bones entering into their formation are fourteen in number: three of the cranium, the frontal, sphenoid, and ethmoid, and all the bones of the face, excepting the malar and lower jaw. Each cavity is bounded by a roof, a floor, an inner and an outer wall.

Upper Wall.—The upper wall, or roof (Fig. 101), is long, narrow, and horizontal in its centre, but slopes downward at its anterior and posterior extremities; it is formed in front by the nasal bones and nasal spine of the frontal, which are directed downward and forward; in the middle, by the cribriform plate of the ethmoid, which is horizontal; and behind, by the under surface of the body of the sphenoid and sphenoidal turbinated bones, the ala of the vomer and the sphenoidal process of the palate bone, which are directed downward and backward. This surface presents, from before backward, the internal aspect of the nasal bones; on their outer side, the suture formed between the nasal bone and the nasal process of the superior maxillary; on their inner side, the elevated crest which receives the nasal spine of the frontal and the perpendicular plate of the ethmoid, and articulates with its fellow of the opposite side; whilst the surface of the bones is perforated by a few small vascular apertures, and presents the longitudinal groove for the nasal nerve; farther back is the transverse suture, connecting the frontal with the nasal in front, and the ethmoid behind, the olfactory foramina and nasal slit on the under surface of the cribriform plate, and the suture between it and the sphenoid behind; quite posteriorly are seen the sphenoidal turbinated bones, the orifices of the sphenoidal sinuses, and the articulation of the alae of the vomer with the under surface of the body of the sphenoid.

Floor (Figs. 84, 100, and 101).—The floor is flattened from before backward, concave from side to side, and wider in the middle than at either extremity. It is formed in front by the palate process of the superior maxillary; behind, by the palate process of the palate bone. This surface presents, from before backward, the anterior nasal spine; behind this, the upper orifices of the anterior palatine canal; internally, the elevated crest which articulates with the vomer; and behind, the suture between the palate and superior maxillary bones, and the posterior nasal spine.

Inner or Medial Wall.—The inner wall, or septum (Figs. 101 and 103), is a thin vertical partition which separates the nasal fossae from each other; it is occasionally perforated, so that the fossae communicate, and it is frequently deflected considerably to one side. It is formed, in front, by the crest of the nasal bones and nasal spine of the frontal; in the middle, by the perpendicular plate of the ethmoid; behind, by the vomer and rostrum of the sphenoid; below, by the crests of the superior maxillary and palate bones. It presents, in front, a large, triangular notch, which receives the septal cartilage of the nose; and behind, the grooved edge of the vomer. Its surface is marked by numerous vascular and nervous canals and the groove for the naso-palatine nerve, and is traversed by sutures connecting the bones of which it is formed.

Outer or Lateral Wall.—The outer wall (Figs. 84 and 101) is formed, in front, by the nasal process of the superior maxillary and lacrimal bones; in the middle,

1 Howard A. Lothrop, in Annals of Surgery, May, 1903.
2 See footnote, p. 99.
by the ethmoid and inner surface of the body of the superior maxillary and inferior turbinated bones; behind, by the vertical plate of the palate bone and the internal pterygoid plate of the sphenoid. Upon this outer wall are two marked projections of bone (Figs. 84 and 101). One is known as the inferior turbinated bone and the other as the middle turbinated bone. The superior turbinated bones or bodies appear as less distinct bony projections. This surface presents three irregular longitudinal passages, or meatuses, termed the superior, middle, and inferior meatuses of the nose (Figs. 84, 101, and 102). The superior meatus (meatus nasi superior), the
smallest of the three, is situated at the upper and back part of each nasal fossa, occupying the posterior third of the outer wall. It is situated between the superior turbinated bone, and has opening into it two foramina, the spheno-palatine foramina at the back of its outer wall, and the posterior ethmoidal cells at the front part of the outer wall. The sphenoidal sinus opens into a recess, the sphen-ethmoidal recess (recessus sphenoethmoidalis), which is situated above and behind the superior turbinated bone. The middle meatus (meatus nasi medius) is situated external to the middle turbinated bone, and above the inferior turbinated bone, and extends from the anterior end of the inferior turbinated bone to the sphenopalatine foramen of the outer wall of the nasal fossa. Anteriorly it terminates in a depression, the atrium of the nasal meatus. The bulla ethmoidalis, an elevated area disclosed by removing the middle turbinated bone. Below and in front of the bulla is a groove, the semilunar hiatus (hiatus semilunaris), into which open the antrum and the anterior ethmoidal cells. The middle meatus presents in front the orifice of the infundibulum (infundibulum ethmoidale), by which the middle meatus communicates with the anterior ethmoidal cells, and through these with the frontal sinuses. The middle ethmoidal cells also open into this meatus, while at the centre of the outer wall is the orifice of the maxillary antrum (hiatus maxillaris), which varies somewhat as to its exact position in different skulls. The inferior meatus (meatus nasi inferior), the largest of the three, is the space between the inferior turbinated bone and the floor of the nasal fossa. It extends along the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower orifice of the canal for the nasal duct (canalis nasolacrimalis). The anterior nares present a heart-shaped or pyriform opening (apertura piriformis) whose long axis is vertical and narrow extremity upward. This opening in the recent state is much contracted by the cartilages of the nose. It is bounded above by the inferior border of the nasal bone; laterally by the thin, sharp margin which separates the facial from the nasal surface of the superior

Fig. 103.—Inner wall of nasal fossa, or septum of nose.
maxillary bone; and below by the same border, where it slopes inward to join its fellow of the opposite side at the anterior nasal spine. The posterior nares, or choanae, are the two posterior oval openings of the nasal fossae, by which they communicate with the upper part of the naso-pharynx. They are situated immediately in front of the basilar process, and are bounded above by the under surface of the body of the sphenoid and alae of the vomer; below, by the posterior border of the horizontal plate of the palate bone; externally, by the inner surface of the internal pterygoid plate; and internally, in the middle line, they are separated from each other by the posterior border of the vomer.

**Difference in Size and Form of the Cranium.**—These differences are thus set forth by Mr. Arthur Thomson in Professor D. J. Cunningham’s *Text-book of Anatomy*:

Microcephalic skulls have a capacity of less than 1350 c.c. Mesocephalic skulls have a capacity of from 1350 c.c. to 1450 c.c. Megacephalic skulls have a capacity over 1450 c.c.

What is known as the cephalic index is the proportion borne by the greatest breadth of the skull to the greatest length, assuming that the latter is equal to 100. Thomson gives the following formula:

\[
\frac{\text{Maximum length} \times 100}{\text{maximum breadth}} = \text{cephalic index.}
\]

The cephalic index is used to determine the form of the skull: Dolichocephalic (long antero-posterior diameter) (Figs. 105 and 107), having a cephalic index

THE ANTERIOR REGION OF THE SKULL

below 75. Mesaticephalic (median head), having a cephalic index from 75 to 80. Brachycephalic (short antero-posterior diameter) (Figs. 104 and 106), having a cephalic index over 80.

Surface Form.—The various bony prominences or landmarks which are to be easily felt and recognized in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follows:

1. Supraorbital arch.
2. Internal angular process.
3. External angular process.
4. Zygomatic arch.
5. Mastoid process.
7. Superior curved line of occipital bone.
8. Parietal eminences.
10. Frontal eminences.
11. Superciliary ridges.
13. Lower margin of orbit.
14. Lower jaw.

1. The supraorbital arches are to be felt throughout their entire extent, covered by the eyebrows. They form the upper boundary of the circumference or base of the orbit, and separate the face from the forehead. They are strong and arched, and terminate internally on each side of the root of the nose in the internal angular process, which articulates with the lachrymal bone. Externally they terminate in the external angular process, which articulates with the malar bone. This arched ridge is sharper and more defined in its outer than in its inner half, and forms an overhanging process which protects and shields the lachrymal gland. It thus protects the eye in its most exposed situation and in the direction from which blows are most likely to come. The supraorbital arch varies in prominence in different individuals. It is more marked in the male than in the female, and in some races of mankind than in others. In the less civilized races, as the forehead recedes backward, the supraorbital arch becomes more prominent, and approaches more to the characters of the monkey tribe, in which the supraorbital arches are very largely developed, and acquire additional prominence from the oblique direction of the frontal bone. 2. The internal angular process is scarcely to be felt. Its position is indicated by the angle formed by the supraorbital arch with the nasal process of the superior maxillary bone and the lachrymal bone at the inner side of the orbit. Between the internal angular processes of the two sides is a broad surface which assists in forming the root of the nose, and immediately above this a broad, smooth, somewhat triangular surface, the glabella, situated between the superciliary ridges. 3. The external angular process is much more strongly marked than the internal, and is plainly to be felt. It is formed by the junction or confluence of the supraorbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does not articulate with the malar, and therefore this lateral support to the bones of the face is not present. 4. The zygomatic arch is plainly to be felt throughout its entire length, being situated almost immediately under the skin. It is formed by the malar bone and the zygomatic process of the temporal bone. At its anterior extremity, where it is formed by the malar bone, it is broad and forms the prominence of the cheek; the posterior part is narrower, and terminates just in front and a little above the tragus of the external ear. The lower border is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the latter, which somewhat obscures its outline. Its shape differs very much in individuals and in different races of mankind. In the most degraded type of skull—as, for instance, in the skull of the negro of the Guinean Coast—the malar bones project forward and not outward, and the zygoma at its posterior extremity extends farther outward before it is twisted on itself to be prolonged forward. This makes the zygomatic arch stand out in bold relief, and affords greater space for the Temporal muscle. In skulls which have a more pyramidal shape, as in the Esquimaux or Greenlander, the malar bones do not project forward and downward under the eyes, as in the preceding form, but take a direction outward, forming with the zygoma a large, rounded sweep or segment of a circle. Thus it happens that if two lines are drawn from the zygomatic arches, touching the temporal ridges, they meet above the top of the head, instead of being parallel, or nearly so, as in the European skull, in which the zygomatic arches are not nearly so prominent. This gives to the face a more or less oval type. 5. Behind the ear is the mastoid portion of the temporal bone, plainly to be felt, and terminating below in a nipple-shaped process. Its anterior border can be traced immediately behind the concha, and its apex is on a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood, and is more marked in the negro than in the European. 6. The external occipital protuberance is always plainly to be felt just at the level where the skin of the neck joins that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. 7. Running outward on either side from the external occipital protuberance is an arched ridge of bone, which can be more or less plainly perceived. This is the superior curved line of the occipital bone, and gives attachment to some of the muscles which
keep the head erect on the spine; accordingly, we find it more developed in the negro tribes, in whom the jaws are much more massive, and therefore require stronger muscles to prevent their extra weight carrying the head forward. Below this line the surface of bone at the back of the head is obscured by the overlying muscles. Above it, the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital, the parietal, and the frontal bones themselves; and in bald persons, even the lines of junction of the bones, especially the junction of the occipital and parietal at the lambdoid suture, may be defined as a slight depression, caused by the thickening of the borders of the bones in this situation. 8. In the line of the greatest transverse diameter of the head, on each side of the middle line, are generally to be found the parietal eminences, one on each side of the middle line, though sometimes these eminences are not situated at the point of the greatest transverse diameter, which is at some other prominent part of the parietal region. They denote the point where ossification of the parietal bone began. They are much more prominent and well-marked in early life, in consequence of the sharper curve of the bone at this period, so that it describes the segment of a smaller circle. Later in life, as the bone grows, the curve spreads out and forms the segment of a larger circle, so that the eminence becomes less distinguishable. In consequence of this sharp curve of the bone in early life, the whole of the vault of the skull has a squarer shape than it has in later life, and this appearance may persist in some rickety skulls. The eminence is more apparent in the negro’s skull than in that of the European. This is due to greater flattening of the temporal fossa in the former skull to accommodate the larger Temporal muscle which exists in these races. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms an arch, so that the force of the blow is diffused over the bone in every direction. 9. At the side of the head may be felt the temporal ridge. Commencing at the external angular process, it may be felt as a curved ridge, passing upward and then curving backward, on the frontal bone, separating the forehead from the temporal fossa. It may then be traced passing backward in a curved direction, over the parietal bone, and, though less marked, still generally to be recognized. Finally, the ridge curves downward, and terminates in the posterior root of the zygoma, which separates the squamous from the subcutaneous mastoid portion of the temporal bone. Sir Victor Horsley has recently shown in an article on the “Topography of the Cerebral Cortex,” that the second temporal ridge (see page 76) can be made out on the living body. 10. The frontal eminences vary a good deal in different individuals, being considerably more prominent in some than in others, and they are often not symmetrical on the two sides of the body, the one being much more pronounced than the other. This is often especially noticeable in the skull of the young child or infant, and becomes less marked as age advances. The prominence of the frontal eminences depends more upon the general shape of the whole bone than upon the size of the protuberances themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright and the frontal eminences stand out in bolder relief. Thus they may be considered as affording, to a certain extent, an indication of the development of the hemispheres of the brain beneath, and of the mental powers of the individual: They are not so much exposed to injury as the parietal eminences. In falls forward the upper extremities are involuntarily thrown out, and break the force of the fall, and thus shield the frontal bone from injury. 11. Below the frontal eminences on the forehead are the superciliary ridges, which denote the position of the frontal sinuses, and vary according to the size of the sinuses in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. They commence on either side of the glabella, and at first present a rounded form, which gradually fades away at their outer ends. 12. The nasal bones form the prominence of the nose. They vary much in size and shape, and to them is due the varieties in the contour of this organ and much of the character of the face. Thus, in the Mongolian or Ethiopian they are flat, broad, and thick at their base, giving to these races the flattened nose by which they are characterized, and differing very decidedly from the Caucasian, in whom the shape of the nasal bones, is narrow, elevated at the bridge, and elongated downward. Below, the nasal bones are thin and connected with the cartilages of the nose, and the angle or arch formed by their union serves to throw out the bridge of the nose, and is much more marked in some individuals than others. 13. The lower margin of the orbit, formed by the superior maxillary bone and the malar bone, is plainly to be felt throughout its entire length. It is continuous internally with the nasal process of the superior maxillary bone, which forms the inner boundary of the orbit. At the point of junction of the lower margin of the orbit with the nasal process is to be felt a little tubercle of bone, which can be plainly perceived by running the finger along the bone in this situation. This tubercle serves as a guide to the position of the lacrimal sac, which is situated above and behind it. 14. The outline of the lower jaw is to be felt throughout its entire length. Just in front of the tragus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened this prominence of bone can be perceived advancing out of the glenoid fossa on to the eminentia articularis, and receding again
when the mouth is closed. From the condyle the posterior border of the ramus can be felt extending down to the angle. A line drawn from the condyle to the angle would indicate the exact position of this border. From the angle to the symphysis of the chin the lower, rounded border of the body of the bone is plainly to be felt. At the point of junction of the two halves of the bone is a well-marked triangular eminence, the mental process, which forms the prominence of the chin.

**Fixed Points for Measurement.**—In order to determine the location of regions of surgical importance within the skull (bony spaces, vessels, fissures, centres, and convolutions of the brain) and in order to estimate cranial capacity, measurements are made and these measurements are taken from fixed points. The following are the chief fixed points:

- **The Nasion.** The middle of the naso-frontal suture.
- **The Glabella.** Midway between the two superciliary ridges.
- **The Obelion.** A point in the sagittal suture between the parietal foramina.
- **The Inion.** The external occipital protuberance.
- **The Basion.** The middle of the anterior edge of the foramen magnum.
- **The Opisthion.** The middle of the posterior edge of the foramen magnum.
- **The Lambda.** The point of junction of the sagittal and lambdoid sutures.
- **The Pterion.** The site of the antero-lateral fontanelle, where the frontal, parietal, squamous portion of the temporal and greater wing of the sphenoid are in relation.
- **The Asterion.** The region of the postero-lateral fontanelle, at the posterior inferior margin of the parietal bone.
- **The Bregma.** The site of the anterior fontanelle, where the sagittal and coronal sutures meet.
- **The Superior Stephanion.** The point where the superior temporal ridge meets the coronal suture.
- **The Inferior Stephanion.** The point where the inferior temporal ridge meets the coronal suture.
- **The Gonion.** The outer surface of the angle of the mandible.
- **The Opisthion.** The middle of the narrowest transverse diameter of the forehead.
- **The Vertex.** The highest point of the vault of the skull.

Besides these points we use the mastoid process, the nasal spine, the zygomatic arch, the frontal eminences, the parietal eminences, the supraorbital ridges, the superciliary ridges, the mental process, suprameatal process, the external and internal angular processes, and the canine fossa.

**Surgical Anatomy.**—The thickness of the skull varies greatly in different regions of the same skull and in different individuals. The average thickness of the skull-cap is about one-fifth of an inch. The thickest portions are the occipital protuberance, the inferior portion of the frontal bone, and the mastoid process. The thinnest portions are the occipital fossae, the squamous portion of the temporal bone, and over certain sinuses and arteries. An arrest in the ossifying process may give rise to deficiencies or gaps, or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margin toward the centre of the bone, but gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Occasionally a protrusion of the brain or its membranes may take place through one of these gaps in an imperfectly developed skull. When the protrusion consists of membranes only, and is filled with cerebro-spinal fluid, it is called a meningocoele; when the protrusion consists of brain as well as membranes, it is termed an encephalocele and when the protruded brain is a prolongation from one of the ventricles, and is distended by a collection of fluid from an accumulation in the ventricle, it is termed an hydrancephalocele. This latter condition is sometimes found at the root of the nose, where a protrusion of the anterior horn of the lateral ventricle takes place through a deficiency of the fronto-nasal suture. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place through the fissures which separate the four centres of ossification from which the tabular portion of the occipital bone is originally developed (see page 75). They most frequently occur through the upper part of the vertical fissure, which is the last to ossify, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions have been met with in other situations than those above mentioned, both through normal fissures, as the sagittal, lambdoid, and other sutures, and also through abnormal gaps and deficiencies at the sides, and even at the base of the skull. Force may be responsible in a young person for separating a suture. This accident, seldom met with even in the young, is only occasionally encountered in older persons.

**Fractures of the skull** may be divided into those of the vault and those of the base. Fractures of the vault are usually produced by direct violence. This portion of the skull varies in thickness and strength in different individuals, but, as a rule, is sufficiently strong to resist a very considerable amount of violence without being fractured. This is due to several causes: the
rounded shape of the head and its construction of a number of secondary elastic arches, each made up of a single bone; the fact that it consists of a number of bones, united, at all events in early life, by a sutural ligament, which acts as a sort of buffer and interrupts the continuity of any violence applied to the skull; the presence of arches or ridges, both on the inside and outside of the skull, which materially strengthen it; and the mobility of the head upon the spine, which further enables it to withstand violence. The elasticity of the bones of the head is especially marked in the skull of the child, and this fact, together with the wide separation of the individual bones from each other, and the interposition between them of other and softer structures render fracture of the bones of the head a very uncommon event in infants and quite young children; as age advances and the bones become joined, fracture is more common, though still less liable to occur than in the adult. Fractures of the vault may, and generally do, involve the *whole thickness* of the bone; but sometimes one table may be fractured without any corresponding injury to the other. Thus, the *outer table* of the skull may be splintered and driven into the diploë, or in the frontal or mastoid regions into the frontal or mastoid cells, without any injury to the internal table. And on the other hand, the *internal table* has been fractured, and portions of it depressed and driven inward, without any fracture of the outer table. As a rule, in fractures of the skull the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inward becomes broken up, and is more diffused by the time it reaches the inner table; the bone, being in the form of an arch, bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch—i.e., the outer table—and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be *simple fissures or starred and comminuted fractures*, and these may be *depressed or elevated*. These latter cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if depressed, a fissure circumscribes the radiating line, enclosing a portion of skull. If this area is circular, it is termed a *pond fracture*, and would in all probability have been caused by a round instrument, as a life-preserver or hammer; if elliptical in shape, it is termed a *gutter fracture*, and would owe its shape to the instrument which had produced it, as a poker. A fracture may take place along the line of an ossified or partly ossified suture. When a surgeon explores the vault of the skull through a wound he must not mistake a Wormian bone for a fragment produced by a fracture. A Wormian bone which may lead to mistake is encountered at the anterior inferior angle of the parietal bone. Wormian bones are most frequently found along the lambdoid suture.

Fractures of the base are most frequently produced by the extension of a fissure from the vault, as in falls on the head, where the fissure starts from the part of the vault which first struck the ground. Sometimes, however, they are caused by direct violence, when foreign bodies have been forced through the thin roof of the orbit, through the cribriform plate of the ethmoid from being thrust up the nose, or through the roof of the pharynx. Other cases of fracture of the base occur from indirect violence, as in fracture of the occipital bone from impaction of the spinal column against its condyles in falls on the buttocks, knees, or feet, or in cases where the glenoid cavity has been fractured by the violent impact of the condyle of the lower jaw against it from blows on the chin.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighborhood of the parietal eminence, it runs downward through the parietal bone and the squamous portion of the temporal bone and across the petrous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa to the middle lacerated foramen of the other side, and may indeed travel round the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise; thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn, and thus permit of the escape of the cerebro-spinal fluid should there be a communication between the internal ear and the tympanum and the membrana tympani be ruptured, as is frequently the case; again, if the fissure passes across the pituitary fossa and the muco-periosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the results of blows on the forehead; but fracture of the cribiform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forward, appears as a subconjunctival ecchymosis. Subcon-
THE ANTERIOR REGION OF THE SKULL 151

Junctival ecchymosis can also be caused by fracture of the malar bone. If the roof of the nasal fossa be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebro-spinal fluid from the nose where the dura mater and arachnoid have been torn. In fractures of the posterior fossa extravasation of blood takes place beneath the deep fascia and discoloration of the skin is soon observed in the course of the posterior auricular artery, the discoloration first appearing in the skin over the tip of the mastoid process of the temporal bone (Battle’s sign). Some of the blood which was extravasated beneath the deep fascia approaches the surface through the openings in the deep fascia for the passage of vessels and nerves.

The bones of the skull are frequently the seat of nodes, and not uncommonly necrosis results from this cause, also from injury. Necrosis may involve the entire thickness of the skull, but is usually confined to the external table. Necrosis of the internal table alone is rarely met with. The bones of the skull are also sometimes the seat of sarcomatous tumor.

The skull in rickets is peculiar: the forehead is high, square, and projecting, and the anterior-posterior diameter of the skull is long in relation to the transverse diameter. The bones of the face are small and ill-developed, and this gives the appearance of a larger head than actually exists. The bones of the head are often thick, especially in the neighborhood of the sutures, and the anterior fontanelle is late in closing, sometimes remaining unclosed till the fourth year. The condition of craniotubes has by some been also believed to be the result of rickets, by others is believed to be due to inherited syphilis. In all probability it is due to both. In these cases the bone undergoes atrophic changes in patches, so that it becomes greatly thinned in places, generally where there is pressure, as from the pillow or nurse’s arm. It is, therefore, usually met with in the parietal bone and vertical plate of the occipital bone.

In congenital syphilis deposits of porous bone are often found at the angles of the parietal bones and two halves of the frontal bone which bound the anterior fontanelle. These deposits are separated by the coronal and sagittal sutures, and give to the skull an appearance like a hot cross bun. They are known as Parrot’s nodes, and such a skull has received the name of natiform, from its fancied resemblance to the buttocks. When the surgeon wishes to effect an entrance into the interior of the mastoid antrum (Fig. 108) he applies his bur or gouge in the suprasmalleal triangle 1 cm. posterior to the suprameatal spine, being careful to keep below the posterior root of the zygomata and the level of the superior wall of the bony meatus. If the instrument is entered at a higher level it will open the cerebral cavity; the instrument should be carried inward, forward, and a little upward, that is, in the direction of the auditory canal. The antrum is usually reached after the penetration of from 1 to 1½ cm. of bone. The depth at which the antrum is situated is not constant. “It is safe to say that if the instrument penetrates deeper than 1½ cm. and be directed too far forward or downward, the horizontal semicircular canal or the aqueductus Fallopian will be encountered. If the former were opened in a purulent otitis media the pus would travel along it to the vestibule and from there into the internal auditory meatus, producing a pachymeningitis or extradural abscess of the posterior fossa of the skull; or from the vestibule through the perpendicular semicircular canal, which if accompanied by erosion of its bony covering would lead to involvement of the meninges of the middle fossa; the same would hold good for the posterior semicircular canal, affecting the posterior fossa. If the latter (the aqueductus Fallopian) were opened an inflammation of the facial nerve which is contained therein would result, producing paralysis of that side of the face. The inflammatory process might also find its way through the entire canal to the internal auditory meatus, causing a pachymeningitis or extradural abscess as mentioned above; or, travelling along the nerve to its cerebral attachment, would produce a meningitis or subdural (intradural) abscess. The direction of the penetrating instrument must also be forward, in order to avoid injuring the lateral sinus” (“Anatomy and Surgery of the Temporal Bone,” by A. E. Schmitt, M.D., American Journal of the Medical Sciences, April, 1903). In the operation for infective thrombosis of the lateral sinus the sinus is deliberately exposed and opened (Fig. 108).
Hartley divides the mastoid process into four parts as follows: The upper margin is the posterior root of the zygoma. The anterior margin is the anterior border of the mastoid. The posterior margin is a vertical line dropped from the masto-occipital junction. The lower margin is an imaginary line backward from the mastoid tip. This space is divided into four equal parts. Points upon it may be designated as on a map. Take the left side for demonstration. An opening in the N. W. quadrant enters the antrum, one into the N. E. quadrant exposes the lateral sinus, one into the S. W. quadrant enters mastoid cells, and a superficial one into the S. E. quadrant enters mastoid cells, but a deep one exposes the descending portion of the lateral sinus.

When pus breaks through the mastoid process it may enter the sheath of the digastric or sternocleido-mastoid muscle and point a considerable distance away from the bone, 

Betzold's abscess.

In connection with the bones of the face a common malformation is cleft palate, owing to the non-union of the palatal processes of the maxillary or pre-oral arch. This cleft may involve the whole or only a portion of the hard palate, and usually involves the soft palate also. The cleft is in the middle line, except it involves the alveolus in front, when it follows the suture between the main portion of the bone and the pre-maxillary bone. Sometimes the cleft runs on either side of the pre-maxillary bone, so that this bone is quite isolated from the maxillary bones and hangs from the end of the vomer. In such a case the pre-maxillary bone usually contains the germs of the central incisors only. In some cases there is no pre-maxillary bone and the great gap in the lip is in the median line. Cleft palate (Fig. 92) is usually associated with hare-lip, which, when single, is almost always on one side, corresponding to the position of the suture between the lateral incisor and canine tooth. Some few cases of median hare-lip have been described. In double hare-lip there is a cleft on each side of the middle line (see page 111).

The outlines and the height of the arch of the palate vary greatly in different persons. A narrow palate with a high arch is common in idiots and certain degenerates.

The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the mandible, and of these the latter is by far the most frequently fractured of all the bones of the face. Fracture of the nasal bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backward or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The malar bone is probably never broken alone; that is to say, unconnected with a fracture of the other bones of the face. The zygomatic arch is occasionally fractured, and when this occurs from direct violence, as is usually the case, the fragments may be displaced inward. This lesion is often attended with great difficulty or even inability to open and shut the mouth, and this has been stated to be due to the depressed fragments perforating the temporal muscle, but would appear rather to be caused by the injury done to the bony origin of the Masseter muscle.

Fractures of the superior maxilla may vary much in degree, from the chipping off of a portion of the alveolar arch, a frequent accident when the "old key" instrument was used for the extraction of teeth, to an extensive commination of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the mandible bone is in the neighborhood of the canine tooth, as at this spot the jaw is weakened by the deep socket for thefang of this tooth; it is next most frequently fractured at the angle; then at the symphysis, and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighborhood of the symphysis to the hyoid bone.

The superior and inferior maxillary bones are both of them frequently the seat of necrosis, though the disease affects the lower much more frequently than the upper jaw. It may be the result of periostitis, from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it not infrequently occurs in children after attacks of the exanthematus fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in the manufacture of matches.

Tumors attack the jaw bones not infrequently, and these may be either innocent or malignant: in the upper jaw cysts may occur in the antrum, constituting the so-called dropsy of the antrum; or, again, cysts may form in either jaw in connection with the teeth; either cysts connected with the roots of fully developed teeth, the "dental cyst;" or cysts connected with imperfectly developed teeth, the "dentigerous cyst." Solid innocent tumors include the fibroma, the chondroma, and the osteoma. Of malignant tumors there are the endotheliomata, the sarcomata, and the epitheliomata. The sarcomata are of various kinds, the spindle-celled, the round-celled, which are of a very malignant character, and the myeloid sarcomata, principally affecting the alveolar margin of the bone. Of the epitheliomata we find the squamous variety spreading to the bone from the palate or gum, and the cylindrical epithelioma originating in the antrum or nasal fossa.
Both superior and inferior maxillary bones occasionally require excision for tumors and in some other conditions. The upper jaw is removed by an incision from the inner canthus of the eye, along the side of the nose, round the ala, and down the middle line of the upper lip. A second incision is carried outward from the inner canthus of the line along the lower margin of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outward and the surface of the bone exposed, and the central incisor of the diseased side is removed. The connections of the bone to the other bones of the face are then divided with a narrow saw and bone-cutting forceps. They are (1) the junction with the malar bone, passing into the sphenomaxillary fissure; (2) the nasal process; a small portion of its upper extremity, connected with the nasal bone in front, the lachrymal bone behind, and the frontal bone above, being left; (3) the connection with the bone on the opposite side and the palate in the roof of the mouth. The bone is now firmly grasped with lion-jaw forceps, and by means of a rocking movement upward and downward the remaining attachments of the orbital plate with the ethmoid and the back of the bone with the palate, broken through. The soft palate is first separated from the hard with a scalpel, and is not removed. Occasionally in removing the upper jaw it will be found that the orbital plate can be spared, and this should always be done if possible. A horizontal saw-cut is to be made just below the infraorbital foramen and the bone cut through with a chisel and mallet. Lockwood has pointed out that in removing the upper jaw the surgeon must be careful in dividing the nasal process of the superior maxilla to preserve the internal orbital or palpebral ligament (Tendo oculi), because this ligament arises from the palpebral fascia, and if it is interfered with the eye will inevitably drop downward. Removal of one-half of the lower jaw is sometimes required. If possible, the section of the bone should be made to one side of the symphysis, so as to save the genial tuberces and the origin of the genio-hyoglossus muscle, as otherwise the tongue tends to fall backward and may produce suffocation. Having extracted the central or preferably the lateral incisor tooth, a vertical incision is made down to the bone, commencing at the free margin of the lip, and carried to the lower border of the bone; it is then carried along its lower border to the angle and up the posterior margin of the ramus to a level with the lobule of the ear. The flap thus formed is raised by separating all the structures attached to the outer surface of the bone. The jaw is now swung through at the point where the tooth has been extracted, and the knife passed along the inner side of the jaw, separating the structures attached to this surface. The jaw is then grasped by the surgeon and strongly depressed, so as to bring down the coronoid process and enable the operator to sever the tendon of the Temporal muscle. The jaw can be now further depressed, care being taken not to evert it nor rotate it outward, which would endanger the internal maxillary artery, and the External pterygoid muscle is torn through or divided. The capsular ligament is now opened in front and the lateral ligaments divided, and the jaw removed with a few final touches of the knife.

The altrum of Highmore occasionally requires tapping for suppuration. This may be done through the socket of a tooth, preferably the first molar, the fangs of which are most intimately connected with the altrum, or through the facial aspect of the bone above the alveolar process. This latter method does not perhaps afford such efficient drainage, but there is less chance of food finding its way into the cavity. The operation may be performed by incising the mucous membrane above the second molar tooth, and driving a trocar or any sharp-pointed instrument into the cavity.

THE HYOID OR LINGUAL BONE (OS HYOIDEUM).

The hyoid bone (Fig. 109) is named from its resemblance to the Greek upsilon; it is also called the lingual bone, because it supports the tongue and gives attachment to its numerous muscles. It is a bony arch, shaped like a horseshoe, and consisting of five segments: a body, two greater cornua, and two lesser cornua. It is suspended from the tip of the styloid processes of the temporal bone by ligamentous bands, the stylo-hyoid ligaments.

Body (corpus ossei hyoidei).—The body, or basi-hyal, forms the central part of the bone, and is of a quadrilateral form.

Surfaces.—Its anterior surface (Fig. 109), convex, directed forward and upward, is divided into two parts by a vertical ridge which descends along the median line and is crossed at right angles by a horizontal ridge, so that this surface is divided into four spaces or depressions. At the point of meeting of these two lines is a prominent elevation, the tubercle. The portion above the horizontal ridge is directed upward, and is sometimes described as the superior border. The anterior surface gives attachment to the Genio-hyoid in the greater part of its extent; above,
to the Genio-hyo-glossus; below, to the Mylo-hyoid, Stylo-hyoid, and aponeurosis of the. Digastric (suprahyoid aponeurosis); and between these to part of the Hyo-glossus. The posterior surface is smooth, concave, directed backward and downward, and separated from the epiglottis by the thyro-hyoid membrane and by a quantity of loose areolar tissue. The lateral surfaces after middle life are joined to the greater cornua. In early life they are connected to the cornua by cartilaginous surfaces, and held together by ligaments, and occasionally a synovial membrane is found between them.

**Borders.**—The superior border is rounded, and gives attachment to the thyro-hyoid membrane, part of the Genio-hyo-glossi and Chondro-glossi muscles. The inferior border gives attachment, in front, to the Sterno-hyoid; behind, to the Omohyoid and to the part of the Thyro-hyoid at its junction with the great cornu. It also gives attachment to the Levatore glandule thyroideae when this muscle is present.

**Greater Cornua (cornua majora).**—The greater cornua or thyro-hyals project backward from the lateral surfaces of the body; they are flattened from above downward, diminish in size from before backward, and terminate posteriorly in a tubercle for the attachment of the lateral thyro-hyoid ligament. The outer surface gives attachment to the Hyo-glossus, their upper border to the Middle constrictor of the pharynx, their lower border to part of the Thyro-hyoid muscle.

**Lesser Cornua (cornua minora).**—The lesser cornua, or cerato-hyals, are two small, conical-shaped eminences attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments. The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

**Development.**—By five centres: one for the body, and one for each cornu. Ossification commences in the body about the eighth month, and in the greater cornua toward the end of foetal life. Ossification of the lesser cornua commences some years after birth. Sometimes there are two centres for the body.

**Attachment of Muscles.**—Sterno-hyoid, Thyro-hyoid, Omohyoid, aponeurosis of the Digastric, Stylo-hyoid, Mylo-hyoid, Genio-hyoid, Genio-hyo-glossus, Chondro-glossus, Hyo-glossus, Middle constrictor of the pharynx, and occasionally a few fibres of the Inferior lingualis. It also gives attachment to the thyro-hyoid membrane and the stylo-hyoid, thyro-hyoid, and hyo-epiglottic ligaments.

**Surface Form.**—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated just below the angle of the jaw. This process of bone is best perceived by making pressure on one cornu, and so pushing the bone over to the opposite side, when the cornu of this side will be distinctly felt immediately beneath the skin. This process of bone is an important landmark in ligature of the lingual artery.

**Surgical Anatomy.**—The hyoid bone is occasionally fractured, generally from direct violence, as in the act of garroting or throttling. It is frequently found broken in those who have been hung. The great cornu is the part of the bone most frequently broken, but sometimes the fracture takes place through the body of the bone. In consequence of the muscles of the

---

1 These ligaments in many animals are distinct bones, and in man are occasionally ossified to a certain extent.
tongue having important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

THE THORAX.

The thorax, or chest, is an osseo-cartilaginous cage the cavity of which (cavum thoracis) contains and protects the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backward, and longer behind than in front. It is somewhat reiform on transverse section.

**Boundaries.**—The posterior surface is formed by the twelve dorsal vertebrae and the posterior part of the ribs. It is concave from above downward, and presents on each side of the middle line a deep groove, the vertebral groove, in consequence of the direction backward and outward which the ribs take from their vertebral extremities to their angles. The anterior surface is flattened or slightly convex, and inclined forward from above downward. It is formed by the sternum and costal cartilages. The lateral surfaces are convex; they are formed by the ribs, separated from each other by spaces. Each space is called an intercostal space (spatium intercostale). These are eleven in number, and are occupied by the intercostal muscles.

The superior or upper opening or aperture of the thorax, the inlet (apertura thoracis superior), is reiform in shape, being broader from side to side than from before backward. It is formed by the first dorsal vertebra behind, the upper margin of the sternum in front, and the first rib on each side. It slopes downward and forward, so that the anterior part of the ring is on a lower level than the posterior. The antero-posterior diameter is about two inches, and the transverse about four. The inferior or lower opening (apertura thoracis inferior) is formed by the twelfth dorsal vertebra behind, by the twelfth rib at the sides, and in front by the cartilages of the eleventh, tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the subcostal angle (angulus infrasternalis), from the apex of which the ensiform cartilage projects. It is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm closes in the opening forming the floor of the thorax.

In the female the thorax differs as follows from the male: 1. Its general capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third dorsal vertebra, whereas in the male it is on a level with the lower part of the body of the second dorsal vertebra. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax than in the male.

The Sternum or Breast Bone.

The sternum (στέρνον, the chest), or breast bone (Figs. 110, 111), is a flat, narrow bone, situated in the median line of the front of the chest, and consisting, in the adult, of three portions. It has been likened to an ancient sword; the upper piece, representing the handle, is termed the manubrium sterni (presternum); the middle and largest piece, which represents the chief part of the blade, is termed the gladiolus (mesosternum or corpus sterni); and the inferior piece, which is likened to the point of the sword, is termed the ensiform or xiphoid process or appendix (processus xiphoideus or metasternum). In early youth the sternum is composed of six pieces or sternebrae. In adult life the upper piece remains as the manubrium; the inferior piece remains as the xiphoid; and the other four pieces fuse together to form the gladiolus. In its
Fig. 110.—Sternum and costal cartilages.

Fig. 111.—Posterior surface of sternum.
natural position its inclination is oblique from above downward and forward. It is slightly convex in front, concave behind, broad above, becoming narrowed at the point where the first and second pieces are connected, after which it again widens a little, and is pointed at its extremity. Its average length in the adult is about seven inches, being rather longer in the male than in the female. At the junction of the manubrium and gladiolus is a distinct angle, the angulus sterni (angle of Ludovic or angle of Louis), the manubrium looking forward, the gladiolus also looking forward, but to a less degree. This angle is on a level with the second rib, and is produced by retraction of the upper portion of the thorax.

First Piece. — The first piece of the sternum, or the manubrium sterni (presternum), is of a somewhat triangular form, broad and thick above, narrow below at its junction with the middle piece.

Surfaces. — Its anterior surface, convex from side to side, concave from above downward, is smooth, and affords attachment on each side to the Pectoralis major and sternal origin of the Sterno-cleido-mastoid muscle. In well-marked bones the ridges limiting the attachment of these muscles are very distinct. Its posterior surface, concave and smooth, affords attachment on each side to the Sterno-hyoid and Sterno-thyroid muscles.

Borders. — The superior border, the thickest, presents at its centre the pre-sternal notch (incisura jugularis), and on each side an oval articular surface, the clavicular facet (incisura clavicularis), directed upward, backward, and outward, for articulation with the sternal end of the clavicle. The inferior border presents an oval, rough surface, covered in the recent state with a thin layer of cartilage, for articulation with the second portion of the bone (synchondrosis sternalis). The junction of the manubrium with the gladiolus is marked by a transverse ridge, which corresponds to the attachment on each side of the cartilage of the second rib. The lateral borders are marked above by a depression (incisura costalis I) for the first costal cartilage, and below by a small facet, which, with a similar facet on the upper angle of the middle portion of the bone, forms a notch (incisura costalis II) for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downward and inward.

Second Piece. — The second piece of the sternum, the corpus sterni or gladiolus (mesosternum), considerably longer, narrower, and thinner than the first piece, is broader below than above.

Surfaces. — Its anterior surface (planum sternale) is nearly flat, directed upward and forward, and marked by three transverse lines which cross the bone opposite the third, fourth, and fifth articular depressions. These lines are produced by the union of the four separate pieces of which this part of the bone consists at an early period of life. At the junction of the third and fourth pieces is occasionally seen an orifice, the sternal foramen; it varies in size and form in different individuals, and pierces the bone from before backward. This surface affords attachment on each side to the sternal origin of the Pectoralis major. The posterior surface, slightly concave, is also marked by three transverse lines, but they are less distinct than those in front: this surface affords attachment below, on each side, to the Triangularis sterni muscle, and occasionally presents the posterior opening of the sternal foramen.

Borders. — The superior border presents an oval surface for articulation with the manubrium. The inferior border is narrow, and articulates with the ensiform appendix. Each lateral border presents, at each superior angle, a small facet, which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; the four succeeding angular depressions receive the cartilages of the third, fourth, fifth, and sixth ribs; whilst each inferior angle presents a small
facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are known as *incisura costales*. They are separated by a series of curved interarticular intervals, which diminish in length from above downward, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the line of junction of two of its primitive component segments. This is well seen in many of the lower animals, where the separate parts of the bone remain ununited longer than in man. In this respect a striking analogy exists between the mode of connection of the ribs with the vertebral column and the connection of the costal cartilages with the sternum.

**Third Piece.**—The third piece of the sternum, the *ensiform* or *xiphoïd appendix* (*processus xiphoïdes* or *metasternum*), is the smallest of the three; it is thin and elongated in form, cartilaginous in structure in youth, but more or less ossified at its upper part in the adult.

**Surfaces.**—Its anterior surface affords attachment to the chondro-xiphoïd ligament; its posterior surface, to some of the fibres of the Diaphragm and Triangularis sterni muscles; its lateral borders, to the aponeurosis of the abdominal muscles. Above it articulates with the lower end of the gladiolus, and at each superior angle presents a facet (*incisura costalis VII*), for the lower half of the cartilage of the seventh rib; below, by its pointed extremity, it gives attachment to the linea alba. This portion of the sternum is very various in appearance, being sometimes pointed, broad, and thin, sometimes bifid or perforated by a round hole, occasionally curved or deflected considerably to one or the other side.

**Structure.**—The bone is composed of delicate cancellous structure, covered by a thin layer of compact tissue, which is thickest in the manubrium between the articular facets for the clavicles.

**Development.**—The cartilaginous sternum originally consists of two bars, situated one on either side of the mesial plane and connected with the rib cartilages of its own side. These two bars fuse with each other along the middle line, and the bone, including the ensiform appendix, is developed by six centres: one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform appendix. Up to the middle of foetal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the middle of the intervals between the articular depressions for the costal cartilages, in the following order (Fig. 112): In the first piece, between the fifth and sixth months; in the second and third, between the sixth and seventh months; in the fourth piece, at the ninth month; in the fifth, within the first year or between the first and second years after birth; and in the ensiform appendix, between the
second and the seventeenth or eighteenth years, by a single centre which makes its appearance at the upper part and proceeds gradually downward. To these may be added the occasional existence, as described by Breschet, of two small episternal centres, which make their appearance one on each side of the pre-sternal notch. They are probably vestiges of the episternal bone of the monotremata and lizards. It occasionally happens that some of the segments are formed from more than one centre, the number and position of which vary (Fig. 114). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper one being the larger; the second piece has seldom more than one; the third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which will serve to explain the occasional occurrence of the sternal foramen (Fig. 113),

or of the vertical fissure which occasionally intersects this part of the bone (Fig. 113), and which is further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed. Union of the various centres of the gladiolus commences about puberty, from below, and proceeds upward, so that by the age of twenty-five they are all united, and this portion of bone consists of one piece. The ensiform cartilage becomes joined to the gladiolus about forty. The manubrium is occasionally but seldom joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, a portion of the centre of the sutural cartilage remaining unossified.

Articulations.—With the clavicles and seven costal cartilages on each side.

Attachment of Muscles.—To nine pairs and one single muscle: the Pectoralis major, Sterno-clido-mastoid, Sterno-hyoid, Sterno-thyroid, Triangularis sterni, aponeuroses of the Obliquus externus, Obliquus internus, Transversalis, Rectus muscles, and Diaphragm.

The Ribs (Costae).

The ribs are elastic arches of bone, which form the chief part of the thoracic walls. They are twelve in number on each side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the spine and in front with the sternum, through the intervention of the costal cartilages; they are called true, sternal, or vertebro-sternal ribs (costa vera). The remaining five are false ribs (costa

---

1 Sir George Humphry states that this is "probably the more complete condition."

2 Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right than on the left side.
spuria); of these, the first three have their cartilages attached to the cartilage of the rib above, and are called the vertebra-chondral ribs; the last two are free at their anterior extremities; they are termed floating or vertebral ribs. The ribs vary in their direction, the upper ones being less oblique than the lower. The extent of obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces are left between them. Each space is called an intercostal space (spatium intercostale). The length of these spaces corresponds to the length of the ribs and their cartilages; their breadth is greater in front than behind, and between the upper than between the lower ribs. The ribs increase in length from the first to the seventh, when they again diminish to the twelfth. In breadth they decrease from above downward; in the upper ten the greatest breadth is at the sternal extremity.

Common Characters of the Ribs.

A rib from the middle of the series should be taken in order to study the common characters of the ribs (Figs. 116, 117, and 118). Each rib presents two extremities, a posterior or vertebral, an anterior or sternal, and an intervening portion — the body or shaft.

**Posterior Extremity.**—The posterior or vertebral extremity presents for examination a head, neck, and tuberosity.

**The Head (capitulum costae).**—The head (Fig. 118) is marked by a kidney shaped articular surface, divided by a horizontal ridge (crista capituli) into two facets for articulation with the costal cavity formed by the junction of the bodies of two contiguous dorsal vertebrae; the upper facet is small, the inferior one of larger size; the ridge separating them serves for the attachment of the interarticular ligament.

**The Neck (collum costae).**—The neck is that flattened portion of the rib which extends outward from the head; it is about an inch long, and is placed in front
of the transverse process of the lower of the two vertebrae with which the head articulates. Its anterior surface is flat and smooth, its posterior surface is rough for the attachment of the middle costo-transverse ligament, and is perforated by numerous foramina, the direction of which is less constant than those found on the inner surface of the shaft. Of its two borders the superior border presents a rough crest (crista colli costae) for the attachment of the anterior costo-transverse ligament; its inferior border is rounded. On the posterior surface of the neck, just where it joins the shaft, and nearer the lower than the upper border, is an eminence—the tuberosity, or tubercle.

Tuberosity (tuberculum costae).—The tuberosity, or tubercle, consists of an articular and a non-articular portion. The articular portion (facies articularis tuberculi costae), the more internal and inferior of the two, presents a small, oval surface for articulation with the extremity of the transverse process of the lower of the two vertebrae to which the head is connected. The non-articular portion is a rough elevation, which affords attachment to the posterior costo-transverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

Anterior Extremity.—The anterior or sternal extremity is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

The Shaft (corpus costae).—The shaft is thin and flat, so as to present two surfaces, an external and an internal, and two borders, a superior and an inferior.

Surfaces.—The external surface is convex, smooth and marked at its back part, a little in front of the tuberosity, by a prominent line, directed obliquely from above downward and outward; this gives attachment to a tendon of the Ilio-costalis muscle or of one of its accessory portions, and is called the angle (angulus costae). At this point the rib is bent in two directions. If the rib is laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, while the portion of the shaft behind the angle is bent inward and at the same time tilted upward. The interval between the angle and the tuberosity increases gradually from the second to the tenth rib. The portion of bone between these two parts is rounded, rough, and irregular, and serves for the attachment of the Longissimus dorsi muscle. The portion of bone between the tubercle and sternal extremity is also slightly twisted upon its own axis, the external surface looking downward behind the angle, a little upward in front of it. This surface presents, toward its sternal extremity, an oblique line, the anterior angle. The internal surface is concave, smooth, directed a little upward behind the angle, a little downward in front of it. This surface is marked by a ridge which com-
mences at the lower extremity of the head; it is strongly marked as far as the inner side of the angle, and gradually becomes lost at the junction of the anterior with the middle third of the bone. The interval between it and the inferior border presents a groove, subcostal groove (sulcus costae), for the intercostal vessels and nerve. At the back part of the bone this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded; it serves for the attachment of the Internal intercostal muscle. The inferior edge corresponds to the lower margin of the rib and gives attachment to the External intercostal muscle. Within the groove are seen the orifices of numerous small foramina which traverse the wall of the shaft obliquely from before backward.

Borders.—The superior border, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front; they serve for the attachment of the External and Internal intercostal muscles. The inferior border, thin and sharp, has attached to it the External intercostal muscle.

Peculiar Ribs.

The ribs which require especial consideration are five in number—viz., the first, second, tenth, eleventh, and twelfth.

First Rib.—The first rib (Fig. 119) is the shortest and the most curved of all the ribs; it is broad and flat, its surface looking upward and downward, and its borders inward and outward. The head is of small size, rounded, and presents only a single articular facet for articulation with the body of the first dorsal vertebra. The neck is narrow and rounded. The tuberosity, thick and prominent, rests on the outer border. There is no angle, but in this situation the rib is slightly bent, with the convexity of the bend upward, so that the head of the bone is directed downward. The upper surface of the shaft is marked by two shallow depressions, separated by a small rough surface (tuberculum scaleni) for the attachment of the Scalenus anticus muscle—the shallow groove in front of it transmitting the subclavian vein, the deeper groove behind it (sulcus subclavia) the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a rough surface, for the attachment of the Scalenus medius muscle. The under surface is smooth, and destitute of the groove observed on the other ribs. The outer border is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the inner is concave, thin, and sharp, and marked about its centre by the commencement of the rough surface for the Scalenus anticus. The anterior extremity is larger and thicker than any of the other ribs.

Second Rib.—The second rib (Fig. 120) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-articular portion of the tuberosity is occasionally only slightly marked. The angle is slight and situated close to the tuberosity, and the shaft is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a similar though slighter bend, with its convexity upward, to that found in the first rib. The shaft is not horizontal, like that of the first rib, its outer surface, which is convex, looking upward and a little outward. It presents, near the middle, a rough eminence, tuberositas costae II, for the attachment of the second and third digitations of the Serratus magnus; behind and above which is attached the Scalenus posterior. The inner surface, smooth and concave, is directed downward and a little inward; it presents a short groove toward its posterior part.

Tenth Rib.—The tenth rib (Fig. 121) has only a single articular facet on its head.

Eleventh and Twelfth Ribs.—The eleventh and twelfth ribs (Figs. 122 and 123) have each a single articular facet on the head, which is of rather large size;
they have no neck or tuberosity, and are pointed at the extremity. The eleventh has a slight angle and a shallow groove on the lower border. The twelfth has neither, and is much shorter than the eleventh, and the head has a slight inclination downward. Sometimes the twelfth rib is even shorter than the first.

Structure.—The ribs consist of cancellous tissue enclosed in a thin, compact layer.

Development.—Each rib, with the exception of the last two, is developed by three centres: one for the shaft, one for the head, and one for the tubercle. The last two have only two centres, that for the tubercle being wanting. Ossification commences in the shaft of the ribs at a very early period, before its appearance in the vertebra. The epiphysis of the head, which is of slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.
Attachment of Muscles.—To nineteen: The Internal and External intercostals, Scalenus anticus, Scalenus medius, Scalenus posticus, Pectoralis minor, Serratus magnus, Obliquus externus, Quadratus lumborum, Diaphragm, Latissimus dorsi, Serratus posticus superior, Serratus posticus inferior, Ilio-costalis, Musculus accessorius ad ilio-costalem, Longissimus dorsi, Cervicalis ascendens, Levatores costarum, and Infracostales.

The Costal Cartilages.

The costal cartilage (cartilago costalis) (Fig. 110) is white, hyaline cartilage. The cartilages serve to prolong the ribs forward to the front of the chest, and they contribute very materially to the elasticity of its walls. The first seven are connected with the sternum, the next three with the lower border of the cartilage of the preceding rib. The cartilages of the last two ribs have pointed extremities, which terminate in free ends in the walls of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. They diminish in breadth, as well as the intervals between them, from the first to the last. They are broad at their attachment to the ribs, and taper toward their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. In direction they also vary: the first descends a little, the second is horizontal, the third ascends slightly, while all the rest follow the course of the ribs for a short extent, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities.

Surfaces.—The anterior surface is convex, and looks forward and upward: that of the first gives attachment to the costo-clavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major.¹ The others are covered by, and give partial attachment to, some of the great flat muscles of the abdomen. The posterior surface is concave, and directed backward and downward, the first giving attachment to the Sterno-thyroid, the third to the sixth inclusive to the Triangularis sterni, and the six or seven inferior ones to the Transversalis muscle and the Diaphragm.

Borders.—Of the two borders, the superior border is concave, the inferior convex; they afford attachment to the internal Intercostal muscles, the upper border of the sixth giving attachment to the Pectoralis major muscle. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate.

Extremities.—Of the two extremities, the outer extremity is continuous with the osseous tissue of the rib to which it belongs. The inner extremity of the first is continuous with the sternum; the six succeeding ones have rounded extremities, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than the true. In old age they become of a deep yellow color, and are prone to calcify.

Attachment of Muscles.—To nine: the Subclavius, Sterno-thyroid, Pectoralis major, Internal oblique, Transversalis, Rectus, Diaphragm, Triangularis sterni, and Internal intercostals.

¹ The first and seventh also, occasionally, give origin to the same muscle.
Surface Form.—The bones of the chest are to a very considerable extent covered by muscles, so that in the strongly developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral region, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the middle line, in front, the superficial surface of the sternum is to be felt throughout its entire length, at the bottom of a deep median furrow situated between the two great pectoral muscles and called the sternal furrow. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous; and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wider at its upper and lower parts, but narrower in the middle. The centre of the upper border of the sternum is visible, constituting the pre-sternal notch, but the lateral parts of this border are obscured by the tendinous origins of the Sterno-mastoid muscles, which present themselves as oblique tendinous cords, which narrow and deepen the notch. Lower down on the subcutaneous surface a well-defined transverse ridge, the angle of Ludovic, is always to be felt. This denotes the line of junction of the manubrium and body of the bone, and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found through its costal cartilage, it is easy to count downward and find any other. From the middle of the sternum the furrow spreads out, and, exposing more of the surface of the body of the bone, terminates below in a sudden depression, the intrasternal depression or pit of the stomach (scrobiculus cordis), which corresponds to the ensiform cartilage. This depression lies between the cartilages of the seventh ribs, and in it the ensiform cartilage may be felt. The sternum in its vertical diameter presents a general convexity forward, the most prominent point of which is at the joint between the manubrium and gladiolus.

On each side of the sternum the costal cartilages and ribs on the front of the chest are partially obscured by the great pectoral muscles; through which, however, they are to be felt as ridges, with yielding intervals between them, corresponding to the intercostal spaces. Of these spaces, the one between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the Pectoralis major muscle corresponds to the fifth rib, and below this, on the front of the chest, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the abdomino-thoracic arch, which is most plainly seen by arching the body backward, is formed by the ensiform cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the eleventh and twelfth ribs or their cartilages.

On each side of the chest, from the axilla downward, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which obscure their outline to a certain extent in the strongly developed. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front and sides of the chest without difficulty. The first rib, being almost completely covered by the clavicle and scapula, can only be distinguished in a small portion of its extent. At the back the angles of the ribs form a slightly-marked oblique line on each side of and some distance from the vertebral spines. This line diverges somewhat as it descends, and external to it is a broad, convex surface caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Surgical Anatomy.—Malformations of the sternum present nothing of surgical importance beyond the fact that abscesses of the mediastinum may sometimes escape through the sternal foramen. Fractures of the sternum are by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages, which support it like so many springs. When broken it is frequently associated with fracture of the spine, and may be caused by forcibly bending the body either backward or forward until the chin becomes impacted against the top of the sternum. It may also be fractured by direct violence or by muscular action. The fracture usually occurs in the upper half of the body of the bone. Dislocation of the gladiolus from the manubrium also takes place, and is sometimes described as a fracture.

The bone, cancellous in structure and being subcutaneous, is frequently the seat of gummatous tumors, and not uncommonly is affected with caries. Occasionally the bone, and especially its ensiform appendix, becomes altered in shape and driven inward by the pressure, in workmen, of tools against the chest.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle of the series are the ones most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth, on account of their loose and floating condition, enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest-wall, and the bone then gives way at its weakest part—i. e., just in front of the angle. But the ribs may also be broken by direct violence, when the bone gives way and is driven inward at the point struck, or they
may be broken by muscular action. It seems probable, however, that in the latter case the bone has undergone some atrophic changes. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity, and this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages may also take place, though it is a comparatively rare injury. The thorax is frequently found to be altered in shape in certain diseases.

The shape of the rickety thorax is produced chiefly by atmospheric pressure. The balance between the air on the inside of the chest and the outside during some stage of respiration is not equal, the preponderance being in favor of the air outside; and this, acting on the softened ribs, causes them to be forced in at the junction of the cartilages with the bones, which is the weakest part. In consequence of this the sternum projects forward, with a deep depression on either side caused by the sinking in of the softened ribs. The depression is less on the left side, on account of the ribs being supported by the heart. The condition is known as pigeon-breast. The lower ribs, however, are not involved in this deformity, as they are prevented from falling in by the presence of the stomach, liver, and spleen. And when the liver and spleen are enlarged, as they sometimes are in rickets, the lower ribs may be pushed outward; this causes a transverse constriction just above the costal arch. The anterior extremities of the ribs are usually enlarged in rickets, giving rise to what has been termed the rickety rosary. The pithetical chest is often long and narrow, flattened from before backward, and with great obliquity of the ribs and projection of the scapulae. In pulmonary empyma the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the barrel-shaped chest. In severe cases of lateral curvature of the spine the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebrae which takes place in this disease the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincident with this, the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind and bulging and convex in front. In addition to this the ribs become occasionally welded together by bony material.

The ribs are frequently the seat of caries leading to abscesses and sinuses, which may burrow to a considerable extent over the wall of the chest. The only special anatomical point in connection with abscesses and sinuses is that care must be taken in dealing with them that the intercostal space is not punctured and the pleural cavity opened or the intercostal vessels wounded, as the necrosed portion of bone is generally situated on the internal surface of the rib.

In cases of empyma the chest requires opening to evacuate the pus. There is considerable difference of opinion as to the best position to do this. Probably the best place for intercostal drainage is between the fifth and sixth ribs, in or a little in front of the mid-axillary line. This is the last part of the cavity to be closed by the expansion of the lung; it is not thickly covered by soft parts; the space between the two ribs is sufficiently great to allow of the introduction of a fair-sized drainage-tube, and when the patient is confined to bed he does not lie upon the drainage-tube as he does when the opening is posterior. Better than intercostal drainage in the vast majority of cases is rib resection and drainage. A portion of the fifth or sixth rib should be removed in the mid-axillary line. In chronic empyma the lung becomes shrunken and adherent and simple drainage will not bring about a cure. It is necessary in such cases to do an operation that will permit of collapse of the chest wall. Eslander's operation consists in resecting a portion of every rib which overlies the cavity of the empyma. Schede's operation consists in removing ribs from the second rib down over the empyma cavity. The ribs are removed from cartilages to angles, and intercostal muscles and the parietal layer of the pleura are also taken away. Fowler and de Lorme not only practice extensive rib resection and remove the parietal layer of the pleura, but also remove the pulmonary pleura (total pleurectomy or pulmonary decortication).

THE EXTREMITIES.

The extremities, or limbs, are those long, jointed appendages of the body which are connected with the trunk by one end and free in the rest of their extent. They are four in number: an upper or thoracic pair, connected with the thorax through the intervention of the shoulder, and subservient mainly toprehension; and a lower pair, connected with the pelvis, intended for support and locomotion. Both pairs of limbs are constructed after one common type, so that they present numerous analogies, while at the same time certain differences are observed between the upper and lower pair, dependent on the peculiar offices they have to perform.
The bones by which the upper and lower limbs are attached to the trunk are named respectively the **shoulder** and **pelvic girdles**, and they are constructed on the same general type, though presenting certain modifications relating to the different uses to which the upper and lower limbs are respectively applied. The shoulder girdle is formed by the **scapulae** and **clavicles**, and is imperfect in front and behind. In front, however, the girdle is completed by the upper end of the sternum, with which the inner extremities of the clavicle articulate. Behind, the girdle is widely imperfect and the scapula is connected to the trunk by muscles only. The pelvic girdle is formed by the **innominate bones**, and is completed in front through the symphysis pubis, at which the two innominate bones articulate with each other. It is imperfect behind, but the intervening gap is filled in by the upper part of the sacrum. The pelvic girdle, therefore, presents, with the sacrum, a complete ring, comparatively fixed, and presenting an arched form which confers upon it a solidity manifestly intended for the support of the trunk, and in marked contrast to the lightness and mobility of the shoulder girdle.

With regard to the morphology of these girdles, the blade of the scapula is generally believed to correspond to the ilium; but with regard to the clavicles there is some difference of opinion: formerly it was believed that they corresponded to the osa pubis, meeting at the symphysis, but it is now generally taught that the clavicle has no homologue in the pelvic girdle, and that the os pubis and ischium are represented by the small coracoid process in man and most mammals.

**THE UPPER EXTREMITY.**

The bones of the upper extremity consist of those of the **shoulder girdle**, of the **arm**, the **forearm**, and the **hand**.

**THE SHOULDER GIRDLE.**

The shoulder girdle consists of the **clavicle** and the **scapula**.

**The Clavicle or Collar Bone (Clavicula).**

The clavicle or **key bone** (*clavis*, a key) obtains its name from its supposed resemblance to the key used by the Romans. It forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates by its inner extremity with the upper border of the sternum, and by its outer extremity with the acromion process of the scapula, serving to sustain the upper extremity in the various positions which it assumes, whilst at the same time it allows of great latitude of motion in the arm.¹ It presents a double curvature when looked at in front, the convexity being forward at the sternal end and the concavity at the scapular end. Its outer third is flattened from above downward, and extends, in the natural position of the bone, from a point opposite the coracoid process to the acromion. Its inner two-thirds are of a prismatic form, and extend from the sternum to a point opposite the coracoid process of the scapula.

**Outer, External, or Flattened Portion.**—The outer third is flattened from above downward, so as to present two surfaces, an upper and a lower; and two borders, an anterior and a posterior.

¹ The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore limbs are used only for progression, but is present for the most part in those animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating with the scapula or sternum.
Surfaces.—The upper surface is flattened, rough, marked by impressions for the attachment of the Deltoid in front and the Trapezius behind; between these two impressions, externally, a small portion of the bone is subcutaneous. The under surface is flattened. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the conoid tubercle (tuberositas coracoidea); this, in the natural position of the bone, surmounts the coracoid process of the scapula and gives attachments to the conoid ligament. From this tubercle an oblique line, occasionally a depression, passes forward and outward to near the outer end of the anterior border; it is called the oblique line or trapezoid ridge, and affords attachment to the trapezoid ligament.

Borders.—The anterior border is concave, thin, and rough, and gives attachment to the Deltoid; it occasionally presents, at its inner end, at the commencement of the deltoid impression, a tubercle, the deltoid tubercle, which is sometimes to be felt in the living subject. The posterior border is convex, rough, broader than the anterior, and gives attachment to the Trapezius.

Inner, Internal, or Prismatic Portion.—The prismatic portion forms the inner two-thirds of the bone. It is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces.

Borders.—The anterior border is continuous with the anterior margin of the flat portion. At its commencement it is smooth, and corresponds to the interval between the attachment of the Pectoralis major and Deltoid muscles; at the inner half of the clavicle it forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The superior border is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. At its commencement it is smooth and rounded, becomes rough toward the inner third for the attachment of the Sterno-mastoid muscle, and terminates at the upper angle of the sternal extremity. The posterior or subclavian border separates the posterior from the inferior surface, and extends from the conoid tubercle to the rhomboid impression. It forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia covering the Omo-hyoid muscle.

Surfaces.—The anterior surface is included between the superior and anterior borders. It is directed forward and a little upward at the sternal end, outward and still more upward at the acromial extremity, where it becomes continuous with the upper surface of the flat portion. Externally, it is smooth, convex, nearly subcutaneous, being covered only by the Platysma; but, corresponding to the inner half of the bone, it is divided by a more or less prominent line into two parts: a lower portion, elliptical in form, rough, and slightly convex, for the attachment of the Pectoralis major; and an upper part, which is rough, for the attachment of the Sterno-cleido-mastoid. Between the two muscular impressions is a small subcutaneous interval. The posterior or cervical surface is smooth, flat, and looks backward toward the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; internally, by the margin of the sternal extremity; externally, it is continuous with the posterior border of the flat portion. It is concave from within outward, and is in relation, by its lower part, with the suprascapular vessels. This surface, at about the junction of the inner and outer curves, is also in close relation with the brachial plexus and subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sterno-hyoid muscle; and presents, at or near the middle, a foramen, nutrient foramen (foramen nutricium). It opens into a canal, nutrient canal (canalis nutricicus), which is directed obliquely outward and transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior, and one on the inferior surface. The inferior or subclavian surface
is bounded, in front, by the anterior border; behind, by the subclavian border. It is narrow internally, but gradually increases in width externally, and is continuous with the under surface of the flat portion. Commencing at the sternal extremity may be seen a small facet, the costal facet, for articulation with the cartilage of the first rib. This is continuous with the articular surface at the sternal end of the bone. External to this is a broad, rough surface, the rhomboid impression (tuberositas costalis), rather more than an inch in length, for the attachment of the costo-clavicular (rhomboid) ligament. The remaining part of this surface is occupied by a longitudinal groove, the subclavian groove, broad and smooth externally, narrow and more uneven internally; it gives attachment to the Subclavius muscle, and by its margins to the costo-coracoid membrane, which splits to enclose the muscle. Not infrequently this groove is subdivided into two parts by a longitudinal line, which gives attachment to the intermuscular septum of the Subclavius muscle.

Internal or Sternal Extremity (extremitas sternalis).—The internal or sternal extremity of the clavicle is triangular in form, directed inward and a little downward and forward; and presents an articular facet (facies articularis sternalis), concave from before backward, convex from above downward, which articulates with the sternum through the intervention of an interarticular fibro-cartilage; the circumference of the articular surface is rough, for the attachment of numerous ligaments. The posterior border of this surface is prolonged backward, so as to increase the size of the articular facet; the upper border gives attachment to the interarticular fibro-cartilage, and the lower border is continuous with the costal facet on the inner end of the inferior or subclavian surface, which articulates with the cartilage of the first rib.

Outer or Acromial Extremity (extremitas acromialis).—The outer or acromial extremity, directed outward and forward, presents a small, flattened, oval facet,
acromial surface (facies articularis acromialis), which looks obliquely downward, for articulation with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromio-clavicular ligaments.

Peculiarities of the Bone in the Sexes and in Individuals.—In the female the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In those persons who perform considerable manual labor, which brings into constant action the muscles connected with this bone, it becomes thicker and more curved, its ridges for muscular attachment become prominently marked. The right clavicle is generally longer, thicker, and rougher than the left.

Structure.—The shaft, as well as the extremities, consists of cancellous tissue, invested in a compact layer much thicker in the middle than at either end. The clavicle is highly elastic, by reason of its curves. From the experiments of Mr. Ward it has been shown that it possesses sufficient longitudinal elastic force to project its own weight nearly two feet on a level surface when a smart blow is struck on it; and sufficient transverse elastic force, opposite the centre of its anterior convexity, to throw its own weight about a foot. This extent of elastic power must serve to moderate very considerably the effect of concussions received upon the point of the shoulder.

Development.—By two centres: one for the shaft and outer extremity and one for the sternal extremity. The centre for the shaft appears very early, before any other bone—according to Béclard, as early as the thirtieth day. The centre for the sternal end makes its appearance about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Articulations.—With the sternum, scapula, and cartilage of the first rib.

Attachment of Muscles.—To six: the Sterno-cleido-mastoid, Trapezius, Pectoralis major, Deltoid, Subclavius, and Sterno-hyoid.

Surface Form.—The clavicle can be felt throughout its entire length, even in persons who are very fat. Commencing at the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Sterno-mastoid a V-shaped notch, the pre-sternal notch. Passing outward, the shaft of the bone can be felt immediately under the skin, with its convexity forward in the inner two-thirds, the surface partially obscured above and below by the attachments of the Sterno-mastoid and Pectoralis major muscles. In the outer third it forms a gentle curve backward, and terminates at the outer end in a somewhat enlarged extremity which articulates with the acromial process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the arm is lying quietly by the side, though in well-developed subjects it may incline a little upward at its outer end. Its direction is, however, very changeable, altering with the varying movements of the shoulder-joint.

Surgical Anatomy.—The clavicle is the most frequently fractured of any single bone in the body. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk. The bone, moreover, is slender, and is very superficial. The bone may be broken by direct or indirect violence or by muscular action. The most common cause is, however, from indirect violence, and the bone then gives way at the junction of the fixed outer one-third with the movable inner two-thirds of the bone. This is the weakest and most slender part of the bone. The fracture is generally oblique, and the displacement of the outer fragments is inward, away from the surface of the body; hence compound fracture of the clavicle is of rare occurrence. The inner fragment as a rule is little displaced (page 503). Beneath the bone the main vessels of the upper limb and the great nerve-cords of the brachial plexus lie on the first rib, and are liable to be wounded in fracture, especially in fracture from direct violence, when the force of the blow drives the broken ends inward. Fortunately, the Subclavius muscle is interposed between these structures and the clavicle, and this often protects them from injury.

The clavicle is not uncommonly the seat of sarcomatous tumors, rendering the operation of excision of the entire bone necessary. This operation is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inward. The removal of the outer part is comparatively easy, but resection of the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.
The Scapula or Shoulder Blade.

The scapula (σκεύαντή, a spade), or blade bone, forms the back part of the shoulder girdle. It is a large, flat bone, triangular in shape, situated at the posterior aspect and side of the thorax, between the second and seventh, or sometimes the eighth, ribs, its internal border or base being about an inch from and nearly but not quite parallel with the spinous processes of the vertebrae, so that it is rather closer to them above than below. It presents for examination two surfaces, three borders, and three angles.

![Diagram of the scapula](image)

Fig. 126.—Left scapula. Anterior surface or venter.

Surfaces. Anterior or Costal Surface, Ventral Aspect or Venter (facies costalis).—The anterior surface (Fig. 126) presents a broad concavity, the subscapular fossa (fossa subscapularis). It is marked, in the inner two-thirds, by several oblique ridges (lineae musculares), which pass from behind outward and upward; the outer third is smooth. The oblique ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Sub-
The anterior third of the fossa, which is smooth, is covered
by, but does not afford attachment to, the fibres of this muscle. The venter is
separated from the internal border by a smooth, triangular margin at the su-
perior and inferior angles, and in the interval between these by a narrow edge which
is often deficient. This marginal surface affords attachment throughout its entire
extent to the Serratus magnus muscle. The subscapular fossa presents a trans-
verse depression at its upper part, where the bone appears to be bent on itself,
forming a considerable angle, called the subscapular angle (angulus sub-
scapularis), thus giving greater strength to the body of the bone from its arched form, whilst
the summit of the arch serves to support the spine and acromion process. It is in
this situation that the fossa is deepest, so that the thickest part of the Subscapu-
laris muscle lies in a line perpendicular to the plane of the glenoid cavity, and
must consequently operate most effectively on the head of the humerus, which
is contained in that cavity. The portion of bone between the suprascapular
notch and the infraglenoid tubercle is sometimes called the surgical neck.

Posterior or Dorsal Surface or Dorsum (facies dorsalis).—The posterior or dorsal
surface (Fig. 127) is arched from above downward, alternately concave and
convex from side to side. It is subdivided unequally into two parts by the
spine; the portion above the spine is called the supraspinous fossa, and that below
it the infraspinous fossa.

The supraspinous fossa (fossa supraspinata), the smaller of the two, is concave,
smooth, and broader at the vertebral than at the humeral extremity. It affords
attachment by its inner two-thirds to the Supraspinatus muscle.

The infraspinous fossa (fossa infraspinata) is much larger than the preceding;
toward its vertebral margin a shallow concavity is seen at its upper part; its centre
presents a prominent convexity, whilst toward the axillary border is a deep groove
which runs from the upper toward the lower part. The inner two-thirds of this
surface affords attachment to the Infraspinatus muscle; the outer third is only cov-
ered by it, without giving origin to its fibres. This surface is separated from the
axillary border by an elevated ridge, which runs from the lower margin of the glenoid
cavity downward and backward to the posterior border, about an inch above the in-
ferior angle. The ridge serves for the attachment of a strong aponeurosis which
separates the Infraspinatus from the two Teres muscles. The surface of bone between
this line and the axillary border is narrow in the upper two-thirds of its extent,
and traversed near its centre by a groove for the passage of the dorsalis scapulae
vessels; it affords attachment to the Teres minor muscle. Its lower third presents a
broader, somewhat triangular surface, which gives origin to the Teres major, and
over which the Latissimus dorsi glides; sometimes the latter muscle takes origin
by a few fibres from this part. The broad and narrow portions of bone above
alluded to are separated by an oblique line which runs from the axillary border,
downward and backward, to meet the elevated ridge; to it is attached the
aponeurosis separating the two Teres muscles from each other.

The spine (spina scapulae) is a prominent plate of bone which crosses obliquely
the inner four-fifths of the dorsum of the scapula at its upper part, and separates the
supra— from the infraspinous fossa: it commences at the vertebral border by a smooth,
triangular surface, over which the Trapezius glides, separated from the bone by a
bursa, and, gradually becoming more elevated as it passes outward, terminates in
the acromion process, which overhangs the shoulder-joint. The spine is triangular
and flattened from above downward, its apex corresponding to the vertebral
border, its base (which is directed outward) to the neck of the scapula. It pre-
sents two surfaces and three borders. Its superior surface is concave, assists in
forming the supraspinous fossa, and affords attachment to part of the Supra-
spinatus muscle. Its inferior surface forms part of the infraspinous fossa, gives
origin to part of the Infraspinatus muscle, and presents near its centre the orifice
of a nutrient canal. Of the three borders, the anterior is attached to the dorsum of the bone; the posterior, or crest of the spine, is broad, and presents two lips and an intervening rough interval. To the superior lip is attached the Trapezius to the extent shown in the figure. A rough tubercle is generally seen occupying that portion of the spine which receives the insertion of the middle and inferior fibres of this muscle. To the inferior lip, throughout its whole length, is attached the Deltoid. The intervals between the lips is also partly covered by the tendinous fibres of these muscles. The external border, or base, the shortest of the three, is slightly concave, its edge thick and round, continuous above with the under surface of the acromion process, below with the neck of the scapula. The narrow portion of bone external to this border, and separating it from the glenoid cavity, is called the great scapular notch, and serves to connect the supra- and infraspinous fossae.
The acromion process (acromion), so called from forming the summit of the shoulder (ἄξιον, a summit; ἀκρός, the shoulder), is a large and somewhat triangular or oblong process, flattened from behind forward, directed at first a little outward, and then curving forward and upward, so as to overhang the glenoid cavity. Its upper surface, directed upward, backward, and outward, is convex, rough, and gives attachment to some fibres of the Deltoid, and in the rest of its extent it is subcutaneous. Its under surface is smooth and concave. Its outer border is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its inner margin, shorter than the outer, is concave, gives attachment to a portion of the Trapezius muscle, and presents about its centre a small oval surface for articulation with the acromial end of the clavicle. Its apex, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coraco-acromial ligament.

Margins or Borders of the Scapula. Superior Border (margo superior).—Of the three borders of the scapula, the superior is the shortest and thinnest; it is concave and extends from the superior angle to the coracoid process. At its outer part is a deep, semicircular notch, the suprascapular notch (incisura scapula), formed partly by the base of the coracoid process. This notch is converted into a foramen by the transverse ligament, and serves for the passage of the suprascapular nerve. Sometimes this foramen is entirely surrounded by bone. The adjacent margin of the superior border affords attachment to the Omo-hyoid muscle.

External or Axillary Border (margo axillaris).—The external or axillary border is the thickest of the three. It commences above at the lower margin of the glenoid cavity, and inclines obliquely downward and backward to the inferior angle. Immediately below the glenoid cavity is a rough impression, the infraglenoid tubercle (tuberositas infraglenoidalis), about an inch in length, which affords attachment to the long head of the Triceps muscle; in front of this is a longitudinal groove, which extends as far as the lower third of the axillary border and affords origin to part of the Subscapularis muscle. The inferior third of this border, which is thin and sharp, serves for the attachment of a few fibres of the Teres major behind and the Subscapularis in front.

Internal or Vertebral Border (margo vertebralis).—The internal or vertebral border, also named the base, is the longest of the three, and extends from the superior to the inferior angle of the bone. It is arched, is intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outward, so as to form an obtuse angle with the lower part. The vertebral border presents an anterior lip, a posterior lip, and an intermediate space. The anterior lip affords attachment to the Serratus magnus; the posterior lip, to the Suprascapularis above the spine, the Infraspinatus below; the interval between the two lips, to the Levator anguli scapula above the triangular surface at the commencement of the spine, the Rhomboideus minor to the edge of that surface; the Rhomboideus major being attached by means of a fibrous arch connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the posterior border.

Angles. Superior or Mesial Angle (angulus medialis).—Of the three angles, the superior, formed by the junction of the superior and internal borders, is thin, smooth, rounded, somewhat inclined outward, and gives attachment to a few fibres of the Levator anguli scapula muscle.

Inferior Angle (angulus inferior).—The inferior angle, thick and rough, is formed by the union of the vertebral and axillary borders, its outer surface affording attachment to the Teres major and frequently to a few fibres of the Latissimus dorsi.

Anterior or Lateral Angle (angulus lateralis).—The anterior angle is the thickest part of the bone, and forms what is called the head of the scapula. The head
presents a shallow, pyriform, articular surface, the glenoid surface or cavity (cavitas glenoidalis, from γλενός, a socket), whose longest diameter is from above downward, and its direction outward and forward. It is broader than above. Just above it is a rough surface, the supraglenoid tubercle or tuberosity (tuberositas supraglenoidalis), to which is attached the long tendon of the Biceps muscle. The glenoid cavity is covered with cartilage in the recent state; and its margins are slightly raised and give attachment to a fibro-cartilaginous structure, the glenoid ligament, by which its cavity is deepened. The anatomical neck of the scapula (collum scapulae) is the slightly depressed surface which surrounds the head; it is more distinct on the posterior than on the anterior surface, and below than above. In the latter situation it has arising from it a thick prominence, the coracoid process.

The coracoid process (processus coracoideus), so called from its fancied resemblance to a crow's beak (κόρας, a crow), is a thick, curved process of bone which arises by a broad base from the upper part of the neck of the scapula; it is directed at first upward and inward, then, becoming smaller, it changes its direction and passes forward and outward. The ascending portion, flattened from before backward, presents in front a smooth, concave surface over which passes the Subscapularis muscle. The horizontal portion is flattened from above downward, its upper surface is convex and irregular, and gives attachment to the Pectoralis minor; its under surface is smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coraco-acromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and of the Coraco-brachialis and gives attachment to the costo-coracoid ligament. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forward and outward on the upper surface of the horizontal portion, an elevated ridge for the attachment of the trapezoid ligament.

Structure.—In the head, processes, and all the thickened parts of the bone the scapula is composed of cancellous tissue, while in the rest of its extent it is composed of a thin layer of dense, compact tissue. The centre part of the supraspinous fossa and the upper part of the infraspinous fossa, but especially the former, are usually so thin as to be semitransparent; occasionally the bone is found wanting in this situation, and the adjacent muscles come into contact.

Development (Fig. 128).—By seven centres. The epiphyses (except one for the coracoid process) appear from fifteen to seventeen years, and unite between twenty-two and twenty-five years of age.
for the inferior angle. Ossification of the body of the scapula commences about the second month of fetal life by the formation of an irregular quadrilateral plate of bone immediately behind the glenoid cavity. This plate extends itself so as to form the chief part of the bone, the spine growing up from its posterior, surface about the third month. At birth a large part of the scapula is osseous, but the glenoid cavity, coracoid and acromion processes, the posterior border, and inferior angle are cartilaginous. From the fifteenth to the eighteenth month after birth ossification takes place in the middle of the coracoid process, which usually becomes joined with the rest of the bone at the time when the other centres make their appearance. Between the fourteenth and twentieth years ossification of the remaining centres takes place in quick succession, and in the following order: first, in the root of the coracoid process, in the form of a broad scale; secondly, near the base of the acromion process; thirdly, in the inferior angle and contiguous part of the posterior border; fourthly, near the extremity of the acromion; fifthly, in the posterior border. The acromion process, besides being formed of two separate nuclei, has its base formed by an extension into it of the centre of ossification which belongs to the spine, the extent of which varies in different cases. The two separate nuclei unite, and then join with the extension from the spine. These various epiphyses become joined to the bone between the ages of twenty-two and twenty-five years. Sometimes failure of union between the acromion process and spine occurs, the junction being effected by fibrous tissue or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union it is probable that the detached segment was never united to the rest of the bone. The upper third of the glenoid cavity is usually ossified from a separate centre (subcoracoid) which makes its appearance between the tenth and eleventh years. Very often, in addition, an epiphysis appears for the lower part of the glenoid cavity.

Articulations.—With the humerus and clavicle.

Attachment of Muscles.—To seventeen: to the anterior surface, the Subscapularis; posterior surface, Supraspinatus, Infraspinatus; spine, Trapezius, Deltoid; superior border, Omo-hyoid; vertebral border, Serratus magnus, Levator anguli scapulae, Rhomboideus minor and major; axillary border, Triceps, Teres minor, Teres major; apex of glenoid cavity, long head of the Biceps; coracoid process, short head of the Biceps, Coraco-brachialis, Pectoralis minor; and to the inferior angle occasionally a few fibres of the Latissimus dorsi.

Surface Form.—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the internal or vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine of the scapula are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromio-clavicular joint by running the finger along it, its position being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backward to join the spine of the scapula. The place of junction is usually denoted by a prominence, which is sometimes called the acromial angle. From here the spine of the scapula can be felt as a prominent ridge of bone, marked on the surface as an oblique depression, which becomes less and less distinct, and terminates a little external to the spinous processes of the vertebrae. Its termination is usually indicated by a slight dimple in the skin on a level with the interval between the third and fourth dorsal spines. Below this point the vertebral border of the scapula may be traced, running downward and outward, and thus diverging from the vertebral spines, to the inferior angle of the bone, which can be recognized, although covered by the Latissimus dorsi muscle. From this angle the axillary border can usually be traced through this thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid process may be felt about an inch below the junction of the middle and outer thirds of the clavicle. Here it is covered by the anterior border of the deltoid and lies a little to the outer side of a slight depression which corresponds to the interval between the Pectoralis major and Deltoid muscles. When the arms are hanging by the side, the upper angle of the scapula corresponds to the upper border of the
second rib or the interval between the first and second dorsal spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth dorsal spines.

Surgical Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased on both surfaces, and the elasticity of the ribs on which it rests. Fracture of the neck of the bone is also uncommon. The most frequent course of a line of fracture of the neck is from the suprascapular notch to the infraglenoid tubercle (surgical neck), and it derives its principal interest from its simulation to a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. A fracture of the neck external to, and not including, the coracoid process (anatomical neck) is said to occur, but it is exceedingly doubtful whether such an accident ever takes place. The acromion process is more frequently broken than any other part of the bone, and there is sometimes, in young subjects, a separation of the epiphysis. It is believed that many of the cases of supposed fracture of the acromion, with fibrous union, which have been found on post-mortem examination are really cases of imperfectly united epiphysis. Sir Astley Cooper believed that most fractures of this bone united by fibrous tissue, and the cause of this mode of union was the difficulty there was in keeping the fractured ends in constant apposition. The coracoid process is occasionally broken off, either from direct violence or perhaps, rarely, from muscular action.

Tumors of various kinds grow from the scapula. Of the innocent form of tumors probably the osteomata are the most common. When an osteoma grows from the center of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. This would appear to afford evidence that this portion of the bone is formed from membrane, and not, like the rest of the bone, from cartilage. Sarcomatous tumors sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. Removal of the upper limb with the scapula and the outer two-thirds of the clavicle is known as the interscapulo-thoracic amputation. The scapula may be partially resected or completely excised. There are several methods of complete excision. The bone may be excised by a T-shaped incision, and, the flaps being reflected, the removal is commenced from the posterior or vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be at once secured.

THE ARM.

The arm is that portion of the upper extremity which is situated between the shoulder and the elbow. Its skeleton consists of a single bone, the humerus.

The Humerus or Upper Arm Bone (Figs. 129, 130).

The humerus (from humerus, or more correctly umerus, the shoulder) is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

Upper Extremity.—The upper extremity presents a large, rounded head, joined to the shaft by a constricted portion, called the neck, and two other eminences, the greater and lesser tuberosities.

The Head (caput humeri).—The head, nearly hemispherical in form, 1 is directed upward, inward, and slightly backward, and articulates with the glenoid cavity of the scapula; its surface is smooth and coated with cartilage in the recent state. The circumference of its articular surface is slightly constricted, and is termed the anatomical neck, in contradistinction to the constriction which exists below the tuberosities. The latter is called the surgical neck (collum chirurgicum), from its often being the seat of fracture. It should be remembered, however, that fracture of the anatomical neck does sometimes, though rarely, occur.

Anatomical Neck (collum anatomicum).—The anatomical neck is obliquely directed, forming an obtuse angle with the shaft. It is more distinctly marked in the lower half of its circumference than in the upper half, where it presents a narrow groove, separating the head from the tuberosities. Its circumference affords

1 Though the head is nearly hemispherical in form, its margin, as Sir G. Humphry has shown, is by no means a true circle. Its greatest measurement is from the top of the bicipital groove in a direction downward, inward, and backward. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upward, outward, and forward.
178

THE SKELETON

Fig. 129.—Left humerus. Anterior view.
attachment to the capsular ligament and is perforated by numerous vascular foramina.

**Greater Tuberosity (tuberculum majus).**—The greater tuberosity is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat facets, separated by two slight ridges; the highest facet gives attachment to the tendon of the Supraspinatus; the middle one, to the Infraspinatus; the inferior facet and the shaft of the bone below it, to the Teres minor. The outer surface of the great tuberosity is convex, rough, and continuous with the outer side of the shaft.

**Lesser Tuberosity (tuberculum minus).**—The lesser tuberosity is more prominent, although smaller than the greater: it is situated in front of the head, and is directed inward and forward. Its summit presents a prominent facet for the insertion of the tendon of the Subscapularis muscle. The tuberosities are separated from one another by a deep groove, the bicipital groove (sulcus intertubercularis). This groove lodges the long tendon of the Biceps muscle, with which runs a branch of the anterior circumflex artery. It commences above between the two tuberosities, passes obliquely downward and a little inward, and terminates at the junction of the upper with the middle third of the bone. It is deep and narrow at the commencement, and becomes shallow and a little broader as it descends. Its borders are called, respectively, the external or posterior bicipital ridge (crista tuberculi majoris) and the internal or anterior bicipital ridge (crista tuberculi minoris), and form the upper part of the anterior and internal borders of the shaft of the bone. In the recent state it is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder joint, and receives the tendon of insertion of the Latissimus dorsi muscle.

**The Shaft (corpus humeri).**—The shaft of the humerus is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

**Anterior Border.**—The anterior border runs from the front of the great tuberosity above to the coronoid depression below, separating the internal from the external surface. Its upper part is very prominent and rough, and forms the outer lip of the bicipital groove. It is sometimes called the posterior bicipital, external bicipital, or pectoral ridge (crista tuberculi majoris), and serves for the attachment of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the rough deltoid eminence or impression (tuberositas deltoidea); below, it is smooth and rounded, affording attachment to the Brachialis anticus muscle.

**External Border (margo lateralis).**—The external border runs from the back part of the greater tuberosity to the external condyle, and separates the external from the posterior surface. It is rounded and indistinctly marked in its upper half, serving for the attachment of the lower part of the insertion of the Teres minor muscle, and below this of the external head of the Triceps muscle; its centre is traversed by a broad but shallow, oblique depression, the musculo-spiral groove (sulcus nervi radialis); its lower part is marked by a prominent, rough margin, a little curved from behind forward, the external supracondylar or epicondylar ridge (margo lateralis), which presents an anterior lip for the attachment of the Supinator longus above and Extensor carpi radialis longior below, a posterior lip for the Triceps, and an intermediate space for the attachment of the external intermuscular septum.

**Internal Border (margo medialis).**—The internal border extends from the lesser tuberosity to the internal condyle. Its upper third is marked by a prominent ridge, forming the posterior lip of the bicipital groove, and gives attachment to the tendon of the Teres major. About its centre is an impression for the attachment of the Coracobrachialis, and just below this is seen the entrance of the
nutrient canal, directed downward. Sometimes there is a second canal situated at the commencement of the musculo-spiral groove, for a nutrient artery derived from the superior profunda branch of the brachial artery. The inferior third of this border is raised into a slight ridge, the internal supraprocondylar or epicondylar ridge (margo medialis), which becomes very prominent below; it presents an anterior lip for the attachment of the Brachialis anticus muscle, a posterior lip for the internal head of the Triceps muscle, and an intermediate space for the attachment of the internal intermuscular septum.

**External Surface (facies anterior lateralis).**—
The external surface is directed outward above, where it is smooth, rounded, and covered by the Deltoid muscle; forward and outward below, where it is slightly concave from above downward, and gives origin to part of the Brachialis anticus muscle. About the middle of this surface is seen a rough, triangular impression for the insertion of the Deltoid muscle, deltoid impression (tuberositas deltoidea); and below it the musculo-spiral groove, directed obliquely from behind, forward and downward, and transmitting the musculo-spiral nerve and superior profunda artery.

**Internal Surface (facies anterior medialis).**—
The internal surface, less extensive than the external, is directed inward above, forward and inward below; at its upper part it is narrow and forms the floor of the bicipital groove; to it is attached the Latissimus dorsi. The middle part of this surface is slightly rough for the attachment of some of the fibres of the tendon of insertion of the Coraco-brachialis; its lower part is smooth, concave from above downward, and gives attachment to the Brachialis anticus muscle.¹ A little below the middle of the shaft is the nutrient foramen (foramen nutricium).

¹ A small, hook-shaped process of bone, the supraprocondylar process, varying from ⅓ to ⅔ of an inch in length, is not infrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal condyle. It is curved downward, forward, and inward, and its pointed extremity is connected to the internal border, just above the inner condyle, by a ligament or fibrous band, which gives origin to a portion of the Pronator radii teres; through the arch completed by this fibrous band the median nerve and brachial artery pass when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery in cases of high division of the brachial. A well-marked groove is usually found behind the process in which the nerve and artery are lodged. This space is analogous to the supraprocondylar foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region. A detailed account of this process is given by Dr. Struthers, in his Anatomical and Observations, p. 202. An accessory portion of the Coraco-brachialis muscle is frequently connected with this process, according to Mr. J. Wood (Journal of Anat. and Phys., No. 1, November, 1866, p. 47).
This leads into a nutrient canal (canalis nutritiosus), which is directed toward the elbow-joint (distally).

**Posterior Surface (facies posterior).**—The posterior surface (Fig. 130) appears somewhat twisted, so that its upper part is directed a little inward, its lower part backward and a little outward. Nearly the whole of this surface is covered by the external and internal heads of the Triceps, the former of which is attached to its upper and outer part, the latter to its inner and back part, the two being separated by the musculo-spiral groove.

**Lower Extremity.**—The lower extremity is flattened from before backward, and curved slightly forward; it terminates below in a broad, articular surface which is divided into two parts by a slight ridge. Projecting on either side are the external and internal condyles (epicondylus lateralis and epicondylus medialis). By some anatomists the external condyle is called the external epicondyle and the internal condyle is called the internal epicondyle. Others call the internal condyle the epitrochlea. The articular surface extends a little lower than the condyles, and is curved slightly forward, so as to occupy the more anterior part of the bone; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, which has received the name of the capitellum, or radial head of the humerus (capitalum humeri); it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone, not extending as far back as the other portion of the articular surface. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is a slight depression, the radial fossa (fossa radialis), which receives the anterior border of the head of the radius when the forearm is flexed. The inner portion of the articular surface, the trochole (trochlea humeri), presents a deep depression between two well-marked borders. This surface is convex from before backward, concave from side to side, and occupies the anterior, lower, and posterior parts of the bone. The external border, less prominent than the internal, corresponds to the interval between the radius and the ulna. The internal border is thicker, more prominent, and consequently of greater length, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna: it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forward and from without inward. Above the front part of the trochlear surface is seen a smaller depression, the coronoid fossa (fossa coronoidae), which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlear surface is a deep, triangular depression, the olecranon fossa (fossa olecrani), in which is received the summit of the olecranon process in extension of the forearm. These fossae are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated by a foramen, the supratrochlear foramen; their upper margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and they are lined, in the recent state, by the synovial membrane of this articulation. The articular surfaces, in the recent state, are covered with a thin layer of cartilage. The external epicondyle (epicondylus lateralis) is a small, tubercular eminence, less prominent than the internal, curved a little forward, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the extensor and supinator muscles. The internal epicondyle (epitrochlea or epicondylus medialis), larger and more prominent, and therefore more liable to fracture, than the external, is directed a little backward: it gives attachment to the internal lateral ligament, to the Pronator radii teres, and to a tendon common
to the origin of some of the flexor muscles of the forearm. The ulnar nerve runs in a groove, the ulnar groove (sulcus nervi ulnaris), at the back of the internal condyle, or between it and the olecranon process. These condyles are directly continuous above with the external and internal supracondylar ridges.

**Structure.**—The extremities consist of cancellous tissue, covered with a thin compact layer; the shaft is composed of a cylinder of compact tissue, thicker at the centre than at the extremities, and hollowed out by a large medullary canal, which extends along its whole length. In the head of the humerus the plates of the cancellous tissue are arranged in curves (Fig. 131) known as **pressure curves.** Most of the bone-plates are at right angles to the plane of the articular surface (the lines of greatest pressure), and they are bound together by other bone-fibres, which usually correspond to the plane of the articular (the lines of greatest tension). This arch-like arrangement strengthens the head of the bone, and it is further strengthened by the binding fibres.

**Development.**—By **seven,** or occasionally **eight,** centres (Fig. 132): one for the shaft, one for the head, one for the tuberosities, one for the radial head, one for the trochlear portion of the articular surface, and one for each condyle. The nucleus for the shaft appears near the centre of the bone in the eighth week, and soon extends toward the extremities. At birth the humerus is ossified nearly in its whole length, the extremities remaining cartilaginous. During the first year, sometimes even before birth, ossification commences in the head of the bone, and during the third year the centre for the tuberosities makes its appearance, usually by a single ossific point, but sometimes, according to Bécnard, by one for each tuberosity, that for the lesser being small and not appearing until the fifth year. By the sixth year the centres for the head and tuberosities have increased in size and become joined, so as to form a single large epiphysis.

The lower end of the humerus is developed in the following manner: At the end of the second year ossification commences in the capitellum, and from this point extends inward, so as to form the chief part of the articular end of the bone,
the centre for the inner part of the trochea not appearing until about the age of twelve. Ossification commences in the internal condyle about the fifth year, and in the external one not until about the thirteenth or fourteenth year. About sixteen or seventeen years the outer condyle and both portions of the articulating surface (which have already joined) unite with the shaft; at eighteen years the inner condyle becomes joined; while the upper epiphysis, although the first formed, is not united until about the twentieth year.

Articulations.—With the glenoid cavity of the scapula and with the ulna and radius.

Attachment of the Muscles.—To twenty-four: to the greater tuberosity, the Supraspinatus, Infraspinatus, and Teres minor; to the lesser tuberosity, the Subscapularis; to the anterior bicipital ridge, the Pectoralis major; to the posterior bicipital ridge, the Teres major; to the bicipital groove, the Latissimus dorsi; to the shaft, the Deltoid, Coraco-brachialis, Brachialis anticus, external and internal heads of the Triceps; to the internal condyle, the Pronator radii teres, and common tendon of the Flexor carpi radialis, Palmaris longus, Flexor sublimis digitorum, and Flexor carpi ulnaris; to the external condyloid ridge, the Supinator longus and Extensor carpi radialis longior; to the external condyle, the common tendon of the Extensor carpi radialis brevior, Extensor communis digitorum, Extensor minimi digiti, Extensor carpi ulnaris, and Supinator brevis; to the back of the external condyle, the Anconeus.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of this bone which are strictly subcutaneous are small portions of the internal and external condyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid muscle. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forward and inward, is to be felt to the inner side of the greater tuberosity, just below the acromio-clavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by placing the finger and making firm pressure just internal to the greater tuberosity; then, by rotating the humerus, the groove will be felt to pass under the finger as the bone is rotated. With the arm abducted from the side, by pressing deeply in the axilla the lower part of the head of the bone is to be felt. On each side of the elbow-joint, and just above it, the internal and external condyles of the bone are to be felt. Of these the internal is the more prominent, but the ridge passing upward from it, the internal condyloid ridge, is much less marked than the external, and, as a rule, is not to be felt. Occasionally, however, we find along this border the hook-shaped process mentioned above. The external condyle is most plainly to be seen during semiflexion of the forearm, and its position is indicated by a depression between the attachment of the adjacent muscles. From it is to be felt a strong bony ridge running up the outer border of the shaft of the bone. This is the external supracondylar ridge; it is concave forward, and corresponds with the curved direction of the lower extremity of the humerus.

Surgical Anatomy.—There are several points of surgical interest connected with the humerus. First, as regards its development. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from this upper epiphysis. Hence, in cases of amputation of the arm in young subjects the humerus continues to grow considerably, and the end of the bone, which immediately after the operation was covered with a thick cushion of soft tissue, begins to project, thinning the soft parts and rendering the stump conical. This may necessitate another operation, which consists in the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place.

There are several points of surgical interest in connection with fractures. First, as regard their causation: the bone may be broken by direct or indirect violence like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other of this class of bone in the body. It is usually the shaft, just below the insertion of the Deltoid, which is thus broken. Mr. Pick has seen the accident happen from throwing a stone, and in an apparently healthy adult from cutting a piece of hard "cake tobacco" on a table. In this latter case there was no disease of the bone that could be discovered. Fractures of the upper end may take place through the anatomical neck, through the surgical neck, or separation of the
greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. These fractures are usually considered to be intracapsular, but they are probably partly within and partly without the capsule, as the lower part of the capsule is inserted some little distance below the anatomical neck, while the upper part is attached to it. They may be impacted or non-impacted. In most cases there is little or no displacement on account of the capsule, in whole or in part, remaining attached to the lower fragment. But occasionally a very remarkable alteration in position takes place; the upper fragment turns on its own axis, so that the cartilaginous surface of the head rests against the upper end of the lower fragment. When the fractured end is entirely separated from all its surroundings, its vascular supply must be entirely cut off, and one would expect it, theoretically, to necrose. But this must be exceedingly rare, for Gurlt was unable to find a single authenticated case recorded. Separation of the upper epiphysis of the humerus sometimes occurs in the young subject, and is marked by a characteristic deformity by which the lesion may be at once recognized. This consists in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower than in the upper part of the bone. The points of interest in connection with these fractures are: (1) That the musculo-spiral nerve may be injured as it lies in the groove on the bone, or may become involved in the callus: which is subsequently thrown out; and (2) the frequency of non-union. This is believed to be more common in the humerus than in any other bone, and various causes have been assigned for it. It would seem most probably to be due to the difficulty that there is in fixing the shoulder-joint and the upper fragment, and possibly the elbow-joint and lower fragment also. Other causes which have been assigned for the non-union are: (1) That in attempting passive motion of the elbow-joint to overcome any rigidity which may exist, the movement does not take place at the articulation, but at the seat of fracture; or that the patient, in consequence of the rigidity of the elbow, in attempting to flex or extend the forearm moves the fragment and not the joint. (2) The presence of small portions of muscular tissue between the broken ends. (3) Want of support to the elbow, so that the weight of the arm tends to drag the lower fragment away from the upper. An important distinction to make in fractures of the lower end of the humerus is between those that involve the elbow-joint and those which do not; the former are always serious, as they may lead to stiffness of the joint and impairment of the utility of the limb. They include the T-shaped fracture and oblique fractures which involve the articular surface. The fractures which do not involve the joint are the transverse above the condyles and the so-called epiphotchlear fracture, in which the tip of the internal condyle is broken off, generally by direct violence.

Under the head of separation of the lower epiphysis two separate injuries have been described: One where the whole of the four ossific centres which form the lower extremity of the bone are separated from the shaft; and secondly, where the articular portion is alone separated, the two condyles remaining attached to the shaft of the bone. The epiphysial line between the shaft and lower end runs across the bone just above the tips of the condyles, a point to be borne in mind in performing the operation of excision. Tumors originating from the humerus are of frequent occurrence. A not uncommon place for a chondroma to grow from is the shaft of the bone somewhere in the neighborhood of the insertion of the deltoid. Sarcomata frequently grow from this bone.

THE FOREARM.

The forearm is that portion of the upper extremity which is situated between the elbow and the wrist. Its skeleton is composed of two bones, the ulna and radius.

The Ulna or Elbow Bone.

The ulna (Figs. 133 and 134), so called from its forming the elbow (ολένα), is a long bone, prismatic in form; placed at the inner side of the forearm, parallel with the radius. It is the larger and longer of the two bones. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; it diminishes in size from above downward, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an interarticular fibro-cartilage. It is divisible into a shaft and two extremities.

Upper Extremity.—The upper extremity, the strongest part of the bone, presents for examination two large, curved processes, the olecranon process and...

the coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

Olecranon Process (olecranon).—The olecranon process (ολέκρανον, elbow; χρυσίον, head) is a large, thick, curved eminence situated at the upper and back part of the ulna. It is curved forward at the summit so as to present a prominent tip which is received into the olecranon fossa of the humerus in extension of the forearm; its base being contracted where it joins the shaft. This is the narrowest part of the upper end of the ulna, and, consequently, the most usual seat of fracture. The posterior surface of the olecranon, directed backward, is triangular, smooth, subcutaneous, and covered by a bursa. Its upper surface is of a quadrilateral form, marked behind by a rough impression for the attachment of the Triceps muscle; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its interior surface is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the great sigmoid cavity. The lateral borders present a continuation of the same groove that was seen on the margin of the superior surface; they serve for the attachment of ligaments—viz., the back part of the internal lateral ligament internally, the posterior ligament externally. To the inner border is also attached a part of the Flexor carpi ulnaris, while to the outer border is attached the Anconeous muscle.

Coronoid Process (processus coronoideus).—The coronoid process (χοροινίδα, anything hooked like a crow's beak) is a triangular eminence of bone which projects horizontally forward from the upper and front part of the ulna. Its base is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its apex is pointed, slightly curved upward, and is received into the coronoid depression of the humerus in flexion of the forearm. Its upper surface is smooth, concave, and forms the lower part of the greater sigmoid cavity. The under surface is concave. At the junction of this surface with the shaft is a rough eminence, the tubercle of the ulna (tuberositas ulnae), for the attachment of the oblique ligament of the superior radio-ulnar articulation and the Brachialis anticus muscle. Its outer surface presents a narrow, oblong, articular depression, the lesser sigmoid cavity. The inner surface, by its prominent, free margin, serves for the attachment of part of the internal lateral ligament. At the front part of this surface is a small, rounded eminence for the attachment of one head of the Flexor sublimis digitorum; behind the eminence, a depression for part of the origin of the Flexor profundus digitorum; and, descending from the eminence, a ridge which gives attachment to one head of the Pronator radii teres. Generally, the Flexor longus pollicis has an origin from the lower part of the coronoid process by a rounded bundle of muscular fibres.

Greater Sigmoid Cavity (incisura semilunaris).—The greater sigmoid cavity, so called from its resemblance to the old shape of the Greek letter Σ, is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the troclear surface of the humerus. About the middle of either lateral border of this cavity is a notch which contracts it somewhat, and serves to indicate the junction of the two processes of which it is formed. The cavity is concave from above downward, and divided into two lateral parts by a smooth, elevated ridge which runs from the summit of the olecranon to the tip of the coronoid process. Of these two portions, the internal is the larger, and is slightly concave transversely; the external portion is convex above, slightly concave below. The articular surface, in the recent state, is covered with a thin layer of cartilage.

Lesser Sigmoid Cavity (incisura radialis).—The lesser sigmoid cavity is a narrow, oblong, articular depression, placed on the outer side of the coronoid process, and receives the lateral articular surface of the head of the radius. It is concave from
THE ULNA

For extensor carpi rad. longior.
Extensor carpi radialis brevior.
Extensor longus pollicis.
Extensor communs digitorum.
Extensor indicis.

Fig. 134.—Bones of the left forearm. Posterior surface.
before backward, and its extremities, which are prominent, serve for the attachment of the orbicular ligament. In the recent state it is covered with a thin layer of cartilage.

The Shaft (corpus ulnae).—The shaft, at its upper part, is prismatic in form, and curved from behind forward and from without inward, so as to be convex behind and externally; its central part is quite straight; its lower part rounded, smooth, and bent a little outward; it tapers gradually from above downward, and presents for examination three borders and three surfaces.

Anterior or Palmar Border (margo volaris).—The anterior border commences above at the prominent inner angle of the coronoid process, and terminates below in front of the styloid process. It is well marked above, smooth and rounded in the middle of its extent, and affords attachment to the Flexor profundus digitorum: its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the attachment of the Pronator quadratus. It separates the anterior from the internal surface.

Posterior or Dorsal Border (margo dorsalis).—The posterior border commences above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and terminates below at the back part of the styloid process; it is well marked in the upper three-fourths, and gives attachment to the aponeurosis common to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor profundus digitorum muscles; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

External or Interosseous Border (crista interossea).—The external or interosseous border commences above by the union of two lines, which converge one from each extremity of the lesser sigmoid cavity, enclosing between them a triangular space for the attachment of part of the Supinator brevis. The external line is the crista m. supinatoris. The interosseous border of the ulna terminates below at the middle of the head of the ulna. Its two middle fourths are very prominent; its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, and separates the anterior from the posterior surface.

Anterior or Palmar Surface (facies volaris).—The anterior surface, much broader above than below, is concave in the upper three-fourths of its extent, and affords attachment to the Flexor profundus digitorum; its lower fourth, also concave, is covered by the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge, directed obliquely from above downward and inward; this ridge, the oblique or pronator ridge, marks the extent of attachment of the Pronator quadratus. At the junction of the upper with the middle third of the bone is the nutrient foramen (foramen nutricium). It opens into the nutrient canal (canalis nutricius), which is directed obliquely upward and inward (proximally).

Posterior or Dorsal Surface (facies dorsalis).—The posterior surface, directed backward and outward, is broad and concave above, somewhat narrower and convex in the middle of its course, narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity, downward to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus muscle, whilst the upper part of the ridge itself affords attachment to the Supinator brevis. The surface of bone below this is subdivided by a longitudinal ridge, sometimes called the perpendicular line, into two parts; the internal part is smooth, and covered by the Extensor carpi ulnaris; the external portion, wider and rougher, gives attachment from above downward to part of the Supinator brevis, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis muscles.

Internal Surface (facies medialis).—The internal surface is broad and concave above, narrow and convex below. It gives attachment by its upper three-fourths
to the Flexor profundus digitorum muscle: its lower fourth is subcutaneous. The anterior and the inner surfaces constitute the flexor surface.

**Lower Extremity.**—The lower extremity of the ulna is of small size, and excluded from the articulation of the wrist-joint. It presents for examination two eminences, the outer and larger of which is a rounded, articular eminence, termed the **head of the ulna** (*capitulum ulnae*), the inner, narrower and more projecting, is a non-articular eminence, the **styloid process** (*processus styloideus*). The head presents an articular facet, part of which, of an oval or semilunar form, is directed downward, and articulates with the upper surface of the interarticular fibro-cartilage which separates it from the wrist-joint; the remaining portion, directed outward, is narrow, convex, and received into the sigmoid cavity of the radius. The peripheral margin of the portion of the head which articulates with the ulna is called the **articular circumference** (*circumferentia articularis*). The **styloid process** projects from the inner and back part of the bone, and descends a little lower than the head, terminating in a rounded summit, which affords attachment to the internal lateral ligament of the wrist. The head is separated from the styloid process by a depression for the attachment of the triangular interarticular fibro-cartilage; and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

**Structure.**—Similar to that of the other long bones.

**Development.**—By three centres: one for the shaft, one for the inferior extremity, and one for the olecranon (Fig. 135). Ossification commences near the middle of the shaft about the eighth week, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year a separate osseous nucleus appears in the middle of the head, which soon extends into the styloid process. About the tenth year ossific matter appears in the olecranon near its extremity, the chief part of this process being formed from an extension of the shaft of the bone into it. At about the sixteenth year the upper epiphysis becomes joined, and at about the twentieth year the lower one.

**Articulations.**—With the humerus and radius.

**Attachment of Muscles.**—To sixteen: to the olecranon, the Triceps, Anconeus, and one head of the Flexor carpi ulnaris. To the coronoid process, the Brachialis anticus, Pronator radii teres, Flexor sublimis digitorum, and Flexor profundus digitorum; generally also the Flexor longus pollicis. To the shaft, the Flexor profundus digitorum, Pronator quadratus, Flexor carpi ulnaris, Extensor carpi ulnaris, Anconeus, Supinator brevis, Extensor ossis metacarpi pollicis, Extensor longus pollicis, and Extensor indicis.

**Surface Form.**—The most prominent part of the ulna on the surface of the body is the olecranon process, which can always be felt at the back of the elbow-joint. When the forearm is flexed, the upper quadrilateral surface can be felt, directed backward; during extension it recedes into the olecranon fossa, and the contracting fibres of the triceps prevent its being perceived. At the back of the olecranon is the smooth, triangular, subcutaneous surface, which below is continuous with the posterior border of the shaft of the bone, and felt in every position of the forearm. During extension the upper border of the olecranon is slightly above the level of the internal condyle, and the process itself is nearer to this condyle than the outer one. Running down the back of the forearm, from the apex of the triangular surface which forms the posterior
surface of the olecranon, is a prominent ridge of bone, the posterior border of the ulna. This is to be felt throughout the entire length of the shaft of the bone, from the olecranon above to the styloid process below. As it passes down the forearm it pursues a sinuous course and inclines to the inner side, so that, though it is situated in the middle of the back of the limb above, it is on the inner side of the wrist at its termination. It becomes rounded off in its lower third, and may be traced below to the small, subcutaneous surface of the styloid process. Internal to this border the lower fourth of the inner surface is to be felt. The styloid process is to be felt as a prominent tubercle of bone, continuous above with the posterior subcutaneous border of the ulna, and terminating below in a blunt apex, which lies a little internal and behind, but on a level with, the wrist-joint. The styloid process is best felt when the hand is in the same line as the bones of the forearm, and in a position midway between supination and pronation. If the forearm is pronated while the finger is placed on the process, it will be felt to recede, and another prominence of bone will appear just behind and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular interarticular fibro-cartilage, and now projects between the tendons of the Extensor carpi ulnaris and the Extensor minimi digiti muscles.

The Radius.

The radius (radius, a ray, or spoke of a wheel) is so called because it is the rotary bone of the forearm. It is situated on the outer side of the forearm, lying side by side with the ulna, which exceeds it in length and size (Figs. 133 and 134). Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist. It is one of the long bones, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

Upper Extremity.—The upper extremity presents a head, neck, and tuberosity.

The Head.—The head (capitulum radii) is of a cylindrical form, depressed on its upper surface into a shallow cup (fovea capituli radii), which articulates with the capitellum or radial head of the humerus. In the recent state it is covered with a layer of cartilage which is thinnest at its centre. Around the circumference of the head is a smooth, articular surface (circumferentia articularis), broad internally where it articulates with the lesser sigmoid cavity of the ulna; narrow in the rest of its circumference, where it rotates within the orbicular ligament. It is coated with cartilage in the recent state. The head is supported on a round, smooth, and constricted portion of bone, called the neck (collum radii), which presents, behind, a slight ridge, for the attachment of part of the Supinator brevis. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the bicipital tuberosity (tuberositas radii). Its surface is divided into two parts by a vertical line—a posterior, rough portion, for the insertion of the tendon of the Biceps muscle; and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The Shaft (corpus radii).—The shaft of the bone is prismatic in form, narrower above than below, and slightly curved, so as to be convex outward. It presents three surfaces, separated by three borders.

Anterior or Palmar Border (margo volaris).—The anterior border extends from the lower part of the tuberosity above to the anterior part of the base of the styloid process below. It separates the anterior from the external surface. Its upper third is very prominent; and from its oblique direction, downward and outward, has received the name of the oblique line of the radius. It gives attachment externally to the Supinator brevis, internally to the Flexor longus pollicis, and between these to the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords attachment to the Pronator quadratus and to the posterior annular ligament of the wrist, and terminates in a small tubercle at the base of the styloid process, into which is inserted the tendon of the Supinator longus.
Posterior or Dorsal Border (margo dorsalis).—The posterior border commences above at the back part of the neck of the radius, and terminates below at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

Internal or Interosseous Border (crista interossea).—The internal or interosseous border commences above at the back part of the tuberosity, where it is rounded and indistinct, becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which descend to the anterior and posterior margins of the sigmoid cavity. This border separates the anterior from the posterior surface, and has the interosseous membrane attached to it throughout the greater part of its extent.

Anterior or Palmar or Flexor Surface (facies volaris).—The anterior surface is concave for its upper three-fourths, and gives attachment to the Flexor longus pollicis muscle; it is broad and flat for its lower fourth, and gives attachment to the Pronator quadratus. A prominent ridge limits the attachment of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle third of this surface is the nutrient foramen (foramen nutritium), the opening of the nutrient canal (canalis nutriticus), which is directed obliquely upward (proximally).

Posterior or Dorsal or Extensor Surface (facies dorsalis).—The posterior surface is rounded, convex, and smooth in the upper third of its extent, and covered by the Supinator brevis muscle. Its middle third is broad, slightly concave, and gives attachment to the Extensor ossis metacarpi pollicis above, the Extensor brevis pollicis below. Its lower third is broad, convex, and covered by the tendons of the muscles, which subsequently run in the grooves on the lower end of the bone.

External Surface (facies lateralis).—The external surface is rounded and convex throughout its entire extent. Its upper third gives attachment to the Supinator brevis muscle. About its centre is seen a rough ridge, for the insertion of the Pronator radii teres muscle. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis muscles.

Lower Extremity.—The lower extremity of the radius is large, of quadrilateral form, and provided with two articular surfaces—one at the extremity, for articulation with the carpus, and one at the inner side of the bone, for articulation with the ulna. The carpal articular surface (facies articularis carpea) is of triangular form, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external is of a triangular form, and articulates with the scaphoid bone; the inner is quadrilateral and articulates with the semilunar bone. The articular surface for the head of the ulna is called the sigmoid cavity of the radius (incisura ulnaris); it is narrow, concave, smooth, and articulates with the head of the ulna. The circumference of this end of the bone presents three surfaces—an anterior, external, and posterior. The anterior surface, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The external surface is prolonged obliquely downward into a strong, conical projection, the styloid process (processus styloideus), which gives attachment by its base to the tendon of the Supinator longus, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, which runs obliquely downward and forward, and gives passage to the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis. The posterior surface is convex, affords attachment to the posterior ligament of the wrist, and is marked by three grooves. Proceeding from without inward, the first groove is broad but shallow, and subdivided into two by a slightly elevated ridge: the outer of these two transmits the tendon of the Extensor carpi radialis
longior, the inner the tendon of the Extensor carpi radialis brevis. The second, which is near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply-defined ridge; it is directed obliquely from above, downward and outward, and transmits the tendon of the Extensor longus pollicis. The third, lying most internally, is a broad groove, for the passage of the tendons of the Extensor indicis and Extensor communis digitornum.

**Structure.**—Similar to that of the other long bones.

**Development (Fig. 136).**—By three centres: one for the shaft and one for each extremity. That for the shaft makes its appearance near the centre of the bone, about the eighth week of foetal life. About the end of the second year ossification commences in the lower epiphysis, and about the fifth year in the upper end. At the age of seventeen or eighteen the upper epiphysis becomes joined to the shaft, the lower epiphysis becoming united about the twentieth year.

**Articulation.**—With four bones: the humerus, ulna, scaphoid, and semilunar.

**Attachment of Muscles.**—To nine: to the tuberosity, the Biceps, to the oblique ridge, the Supinator brevis, Flexor sublimis digitornum, and Flexor longus pollicis; to the shaft (its anterior surface), the Flexor longus pollicis and Pronator quadratus; (its posterior surface), the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; (its outer surface), the Pronator radii teres; and to the styloid process, the Supinator longus.

**Surface Form.**—Just below and a little in front of the posterior surface of the external condyle a part of the head of the radius may be felt, covered by the orbicular and external lateral ligaments. There is in this situation a little dimple in the skin, which is most visible when the arm is extended, and which marks the position of the head of the bone. If the finger is placed on this dimple and the forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft of the radius cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half of the shaft can be readily examined, though covered by tendons and muscles and not strictly subcutaneous. If traced downward, the shaft will be felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inward toward the wrist. About the middle of the posterior aspect of the lower extremity of the bone is a well-marked ridge, best perceived when the hand is slightly flexed on the wrist. It forms the outer boundary of the oblique groove on the posterior surface of the bone, through which the tendon of the Extensor longus pollicis runs, and serves to keep that tendon in place.

**Surgical Anatomy of the Radius and Ulna.**—The two bones of the forearm are more often broken together than is either the radius or ulna separately. It is therefore convenient to consider fractures of both bones in the first instance, and subsequently to mention the principal fractures which take place in each bone individually. These fractures may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius generally alone gives way, though both bones may suffer. The fracture from indirect force generally takes place somewhere about the middle of the bones; fracture from direct violence may occur at any part, more often, however, in the lower half of the bone. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency that there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other, and therefore diminishes the risk of the bones
becoming united across the interosseous membrane. The splints, anterior and posterior, which are applied in these cases should be rather wider than the limb, so as to prevent any lateral pressure on the bones. In these cases there is a greater liability to gangrene from the pressure of the splints than in other parts of the body. This is no doubt due principally to two causes: (1) the flexion of the forearm compressing to a certain extent the brachial artery and retarding the flow of blood to the limb; and (2) the superficial position of the two main arteries of the forearm in a part of their course, and their liability to be compressed by the splints. The special fractures of the ulna are—(1) Fracture of the olecranon. This may be caused by direct violence, falls on the elbow, with the forearm flexed, or by muscular action by the sudden contraction of the triceps. The most common place for the fracture to occur is at the constriction portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. The displacement is sometimes very slight, owing to the fibrous structures around the process not being torn. (2) Fracture of the coronoid process sometimes occurs as a complication of dislocation backward of the bones of the forearm, but it is doubtful if it ever occurs as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually takes place at the middle of the bone or a little below it. They are almost always the result of direct violence. (4) The styloid process may be knocked off by direct violence. Fractures of the radius consist of—(1) Fracture of the head of the bone; this generally occurs in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck may also take place, but is generally complicated with other injury. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. They may take place from either direct or indirect violence. In fractures of the upper third of the shaft of the bone, that is to say, above the insertion of the Pronator radii teres, the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator brevis, and flexed by the Biceps; while the lower fragment is pronated and drawn toward the ulna by the two pronators. If such a fracture is put up in the ordinary position, midway between supination and pronation, the fracture will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movements of the hand will result. The limb should be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles’s fracture). The fracture is transverse, and generally takes place about an inch from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than the male. In consequence of the manner in which the fracture is caused, the upper fragment becomes driven into the lower, and impaction is the result; or else the lower fragment becomes split up into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles’s fracture may be distinguished from other injuries in this neighborhood—especially dislocation, with which it is liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna; that is to say, nearer the ground. After fracture or separation of the epiphysis this process is on the same or a higher level than that of the ulna, whereas it would be unaltered in position in dislocation.

THE HAND.

The skeleton of the hand is subdivided into three segments—the carpus or wrist bones; the metacarpus or bones of the palm; and the phalanges or bones of the digits.

The Carpus (Ossa Carpi) (Figs. 137, 138).

The bones of the carpus (καρπός, the wrist), eight in number, are arranged in two rows. Those of the upper row, enumerated from the radial to the ulnar side, are the scaphoid, semilunar, cuneiform, and pisiform; those of the lower row, enumerated in the same order, are the trapezium, trapezoid, os magnum, and unciform.

Common Characters of the Carpal Bones.—Each bone (excepting the pisiform) presents six surfaces. Of these the anterior, palmar, or volar, and the posterior or dorsal are rough for ligamentous attachment, the dorsal surface being the broader, except in the scaphoid and semilunar. The superior or proximal and inferior or distal are articular, the superior generally convex, the inferior concave; and the
internal and external are also articular when in contact with contiguous bones, otherwise rough and tubercular. The structure in all is similar, consisting of cancellous tissue enclosed in a layer of compact bone. Each bone is also developed from a single centre of ossification.
Bones of the Upper Row.

Scaphoid or Navicular Bone (os naviculare manus, the boat-like bone) (Fig. 139).—The scaphoid (σκάφος, a boat, σπόρος, like) is the largest bone of the first row. It has received its name from its fancied resemblance to a boat, being broad at one end and narrowed like a prow at the opposite. It is situated at
the upper and outer part of the carpus, its long axis being from above downward, outward, and forward.

**Surfaces.**—The *superior surface* is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The *inferior surface*, directed downward, outward, and backward, is smooth, convex, also triangular, and divided by a slight ridge into two parts, the external of which articulates with the trapezium, the inner with the trapezoid. The *posterior or dorsal surface* presents a narrow, rough groove which runs the entire length of the bone and serves for the attachment of ligaments. The *anterior or palmar surface* is concave above, and elevated at its lower and outer part into a prominent rounded *tuberosity* (*tuberculum ossis navicularis*), which projects forward from the front of the carpus and gives attachment to the anterior annular ligament of the wrist and sometimes a few fibres of the Abductor pollicis. The *external surface* is rough and narrow, and gives attachment to the external lateral ligament of the wrist. The *internal surface* presents two articular facets: of these, the superior or smaller one is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming, with the semilunar bone, a concavity for the head of the os magnum.

To ascertain to which side the bone belongs, hold it with the superior or radial convex, articular surface upward, and the posterior surface—i.e., the narrow, non-articular, grooved surface—toward you. The tubercle on the outer surface points to the side to which the bone belongs.¹

**Articulations.**—With five bones: the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

**Attachment of Muscles.**—Occasionally a few fibres of the Abductor pollicis.

**Semilunar (os lunatum)** (Fig. 140).—The semilunar (*semi*, half; *luna*, moon) bone may be distinguished by its deep concavity and crescentic outline. It is situated in the centre of the upper row of the carpus, between the scaphoid and cuneiform.

**Surfaces.**—The *superior surface*, convex, smooth, and bounded by four edges, articulates with the radius. The *inferior surface* is deeply concave, and of greater

1 In these directions each bone is supposed to be placed in its natural position—that is, such a position as it would occupy when the arm is hanging by the side, the forearm in a position of supination, the thumb being directed outward, and the palm of the hand looking forward.
extent from before backward than transversely: it articulates with the head of the os magnum and by a long, narrow facet (separated by a ridge from the general surface) with the unciform bone. The anterior or palmar and posterior or dorsal surfaces are rough, for the attachment of ligaments, the former being the broader and of a somewhat rounded form. The external surface presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The internal surface is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

Hold it with the convex articular surface for the radius upward, and the narrowest non-articular surface toward you. The semilunar facet for the scaphoid will be on the side to which the bone belongs.

Articulations.—With five bones: the radius above, os magnum and unciform below, scaphoid and cuneiform on either side.

Cuneiform (os triquetrum, the wedge-shaped bone) (Fig. 141).—The cuneiform (cuneus, a wedge; forma, likeness) may be distinguished by its pyramidal shape, and by its having an oval, isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus.

Surfaces.—The superior surface presents an internal, rough, non-articular portion, and an external or articular portion, which is convex, smooth, and articulates with the triangular interarticular fibro-cartilage of the wrist. The inferior surface, directed outward, is concave, sinuously curved, and smooth for articulation with the unciform. The posterior or dorsal surface is rough, for the attachment of ligaments. The anterior or palmar surface presents, at its inner side, an oval facet, for articulation with the pisiform; and is rough externally, for ligamentous attachment. The external surface, the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The internal surface, the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

Hold the bone with the surface supporting the pisiform facet away from you, and the concavo-convex surface for the unciform downward. The base of the wedge (i.e., the broad end of the bone) will be on the side to which it belongs.

Articulations.—With three bones: the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibro-cartilage which separates it from the lower end of the ulna.

Pisiform (os pisiforme) (Fig. 142).—The pisiform (pisum, a pea; forma, likeness) may be known by its small size and by its presenting a single articular facet. It is situated on a plane anterior to the other bones of the carpus; it is spheroidal in form, with its long diameter directed vertically.

Surfaces.—Its posterior surface is a smooth, oval facet, for articulation with the cuneiform. This facet approaches the superior, but not the inferior border of the bone. The anterior or palmar surface is rounded and rough, and gives attachment to the anterior annular ligament and to the Flexor carpi ulnaris and Abductor minimi digiti muscles. The outer and inner surfaces are also rough, the former being concave, the latter usually convex.

Hold the bone with the posterior surface—that which presents the articular facet—toward you, in such a manner that the faceted portion of the surface is uppermost. The outer, concave surface will point to the side to which it belongs.

Articulations.—With one bone, the cuneiform.

Attachment of Muscles.—To two: the Flexor carpi ulnaris and Abductor minimi digiti; and to the anterior annular ligament.
Bones of the Lower Row.

Trapezium (os multangulum majus) (Fig. 143).—The trapezium (τράπεζα, a table) is of very irregular form. It may be distinguished by a deep groove, for the tendon of the Flexor carpi radialis muscle. It is situated at the external and inferior part of the carpus between the scaphoid and first metacarpal bone.

Surfaces.—The superior surface, concave and smooth, is directed upward and inward, and articulates with the scaphoid. The inferior surface, directed downward and inward, is oval, concave from side to side, convex from before backward, so as to form a saddle-shaped surface, for articulation with the base of the first metacarpal bone. The anterior or palmar surface is narrow and rough. At its upper part is a deep groove running from above obliquely downward and inward; it transmits the tendon of the Flexor carpi radialis, and is bounded externally by a prominent ridge, the oblique ridge of the trapezium (tuberculum ossis multanguli majoris). This surface gives attachment to the Abductor pollicis, Flexor ossis metacarpi pollicis, and Flexor brevis pollicis muscles, and the anterior annular ligament. The posterior or dorsal surface is rough. The external surface is also broad and rough, for the attachment of ligaments. The internal surface presents two articular facets: the upper one, large and concave, articulates with the trapezoid; the lower one, small and oval, with the base of the second metacarpal bone.

Hold the bone with the saddle-shaped surface downward and the grooved surface away from you. The prominent, rough, non-articular surface points to the side to which the bone belongs.

Articulations.—With four bones: the scaphoid above, the trapezoid and second metacarpal bones internally, the first metacarpal below.

Attachment of Muscles.—Abductor pollicis, Flexor ossis metacarpi pollicis, and part of the Flexor brevis pollicis.

Trapezoid (os multangulum minus) (Fig. 144).—The trapezoid is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow end the palmar, surface, and by its having four articular surfaces touching each other and separated by sharp edges.

Surfaces.—The superior surface, quadrilateral in form, smooth, and slightly concave, articulates with the scaphoid. The inferior surface articulates with the upper
end of the second metacarpal bone; it is convex from side to side, concave from before backward, and subdivided by an elevated ridge into two unequal lateral facets. The posterior or dorsal and anterior or palmar surfaces are rough, for the attachment of ligaments, the former being the larger of the two. The external surface, convex and smooth, articulates with the trapezium. The internal surface is concave and smooth in front, for articulation with the os magnum; rough behind, for the attachment of an interosseous ligament.

Hold the bone with the larger, non-articular surface toward you, and the smooth, quadrilateral articular surface upward. The convex articular surface will point to the side to which the bone belongs.\(^1\)

Articulations.—With four bones: the scaphoid above, second metacarpal bone below, trapezium externally, os magnum internally.

Os Magnum (*os capitatum*) (Fig. 145).—The os magnum is the largest bone of the carpus, and occupies the centre of the wrist. It presents, above, a rounded

Fig. 145.—The left os magnum.

portion or head, which is received into the concavity formed by the scaphoid and semilunar bones; a constricted portion or neck; and, below, the body.

Surfaces.—The superior surface is rounded, smooth, and articulates with the semilunar. The inferior surface is divided by two ridges into three facets for articulation with the second, third, and fourth metacarpal bones, that for the third (the middle facet) being the largest of the three. The posterior or dorsal surface is broad and rough; the anterior or palmar, narrow, rounded, and also rough, for the attachment of ligaments and a part of the Adductor obliquus pollicis. The external surface articulates with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Above this is a deep and rough groove, which forms part of the neck and serves for the attachment of ligaments, bounded superiorly by a smooth, convex surface, for articulation with the scaphoid. The internal surface articulates with the unciform by a smooth, concave, oblong facet which occupies its posterior and superior parts, and is rough in front, for the attachment of an interosseous ligament.

Hold the bone with the broader, non-articular surface toward you, and the head upward. The small, articular facet at the anterior inferior angle of the external surface will point to the side to which the bone belongs.

Articulations.—With seven bones: the scaphoid and semilunar above; the second, third, and fourth metacarpal below; the trapezoid on the radial side; and the unciform on the ulnar side.

Attachment of Muscles.—Part of the Adductor obliquus pollicis.

Unciform (*os hamatum*) (Fig. 146).—The unciform or hook bone (*uncus*, a hook; *forma*, likeness) may be readily distinguished by its wedge-shaped form and the hook-like process that projects from its palmar surface. It is situated at the inner

---

\(^1\) Occasionally in a badly marked bone there is some difficulty in ascertaining to which side the bone belongs; the following method will sometimes be found useful: Hold the bone with its broader, non-articular surface upward, so that its sloping border is directed toward you. The border will slope to the side to which the bone belongs.
and lower angle of the carpus, with its base downward, resting on the two inner metacarpal bones, and its apex directed upward and outward.

**Surfaces.**—The *superior surface*, the apex of the wedge, is narrow, convex, smooth, and articulates with the semilunar. The *inferior surface* articulates with

the fourth and fifth metacarpal bones, the concave surface for each being separated by a ridge which runs from before backward. The *posterior or dorsal surface* is triangular and rough, for ligamentous attachment. The *anterior or palmar surface* presents, at its lower and inner side, a curved, hook-like process of bone, the *unciform process* (*hamulus ossis hamati*), directed from the palmar surface forward and outward. It gives attachment by its apex to the annular ligament and Flexor carpi ulnaris; by its inner surface to the Flexor brevis minimi digiti and the Opponens minimi digiti; and is grooved on its outer side, for the passage of the Flexor tendons into the palm of the hand. This is one of the four eminences on the front of the carpus to which the anterior annular ligament is attached, the others being the pisiform internally, the oblique ridge of the trapezium and the tuberosity of the scaphoid externally. The *internal surface* articulates with the cuneiform by an oblong facet cut obliquely from above, downward and inward. The *external surface* articulates with the os magnum by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

Hold the bone with the hooked process away from you, and the articular surface, divided into two parts, for the metacarpal bones, downward. The concavity of the process will be on the side to which the bone belongs.

**Articulations.**—With five bones: the semilunar above, the fourth and fifth metacarpal below, the cuneiform internally, the os magnum externally.

**Attachment of Muscles.**—To three: the Flexor brevis minimi digiti, the Opponens minimi digiti, the Flexor carpi ulnaris.

**The Metacarpus (Ossa Metacarpalia)** (Figs. 137, 138).

The metacarpal bones are five in number, and they are numbered from 1 to 5 inclusive, the first being the metacarpal bone of the thumb, the fifth the metacarpal bone of the index finger. They are long, cylindrical bones, presenting for examination a shaft and two extremities.

**Common Characters of the Metacarpal Bones. The Shaft (corpus).**—The shaft is prismoid in form and curved longitudinally, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces: two lateral and one posterior. The two lateral surfaces constitute the *palmar* or *volar surface*. The *lateral surfaces* are concave, for the attachment of the Intersossei muscles, and separated from one another by a prominent anterior ridge. The *posterior or dorsal surface* presents in its distal half a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This triangular surface is bounded by two lines, which commence in
small tubercles situated on the dorsal aspect on either side of the digital extremity, and, running backward, converge to meet together a little behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral, sloping surfaces for the attachment of the Dorsal interossei muscles. To the tubercles on the digital extremities are attached the lateral ligaments of the metacarpophalangeal joints. On the palmar surface of each metacarpal bone is a nutrient foramen (foramen nutricium), which opens into a nutrient canal (canalis nutricius). In the thumb metacarpal the direction of this foramen is toward the periphery (distally). In each of the other metacarpals it is from the periphery (proximally).

Carpal or Proximal Extremity or Base (basis).—The carpal extremity, or base, is of a cuboidal form, and broader behind than in front; it articulates above with the carpus, and on each side with the adjoining metacarpal bones; its dorsal and palmar surfaces are rough, for the attachment of tendons and ligaments.

Digital or Distal Extremity or Head (capitulum).—The digital extremity, or head, presents an oblong surface, markedly convex from before backward, less so from side to side, and flattened laterally; it articulates with the proximal phalanx; it is broader and extends farther forward on the palmar than on the dorsal aspect. It is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpo-phalangeal joint. The posterior surface, broad and flat, supports the Extensor tendons; the anterior surface is grooved in the middle line for the passage of the Flexor tendons, and marked on each side by an articular eminence continuous with the terminal articular surface. The metacarpal spaces (spatia interossea metacarpi) are the intervals between the metacarpal bones. They are occupied by the Interossei muscles. The broadest space is between the metacarpal bones of the thumb and index finger.

Peculiar Characters of the Metacarpal Bones.—The Metacarpal Bone of the Thumb (os metacarpale I) (Fig. 147) is shorter and wider than the rest, diverges to a greater degree from the carpus, and its palmar surface is directed inward toward the palm. The shaft is flattened and broad on its dorsal aspect, and does not present the ridge which is found on the other metacarpal bones; it is concave from above downward, on its palmar surface. The carpal extremity, or base, presents a concavo-convex surface, for articulation with the trapezium; it has no lateral facets, but presents externally a tubercle for the insertion of the Extensor ossis metacarpi pollicis. The digital extremity is less convex than that of the other metacarpal bones, broader from side to side than from before backward. It presents on its palmar aspect two distinct articular eminences for the two sesamoid bones in the tendons of the Flexor brevis pollicis, the outer one being the larger of the two.

The side to which this bone belongs may be known by holding it in the position it occupies in the hand, with the carpal extremity upward and the dorsal surface backward; the tubercle for the Extensor ossis metacarpi pollicis will point to the side to which it belongs.

Attachment of Muscles.—To four: the Flexor ossis metacarpi pollicis, the Extensor ossis metacarpi pollicis, the Flexor brevis pollicis, and the First dorsal interosseous.

---

1 By these sloping surfaces the metacarpal bones of the hand may be at once differentiated from the metatarsal bone of the foot.
The **Metacarpal Bone of the Index Finger** (*os metacarpace II*) (Fig. 148) is the longest and its base the largest of the other four. Its **carpal extremity** is prolonged upward and inward, forming a prominent ridge. The dorsal and palmar surfaces of this extremity are rough, for the attachment of tendons and ligaments. It presents four articular facets: three on the upper aspect of the base: the middle one of the three is the largest, concave from side to side, convex from before backward, for articulation with the trapezoid; the external one is a small, flat, oval facet, for articulation with the trapezium; the internal one on the summit of the ridge is long and narrow, for articulation with the *os magnum*. The fourth facet is on the inner or ulnar side of the extremity of the bone, and is for articulation with the third metacarpal bone.

The side to which this bone belongs is indicated by the absence of the lateral facet on the outer (radial) side of its base, so that if the bone is placed with the base toward the student and the palmar surface upward, the side on which there is no lateral facet will be that to which it belongs.

**Attachment of Muscles.**—To *six*: Flexor carpi radialis, Extensor carpi radialis longior, Adductor obliquus pollicis, First and Second dorsal interosseous, and First palmar interosseous.

The **Metacarpal Bone of the Middle Finger** (*os metacarpace III*) (Fig. 149) is a little smaller than the preceding: it presents a pyramidal eminence, the **styloid process** (*processus styloideus*), on the radial side of its base (dorsal aspect), which extends upward behind the *os magnum*; immediately below this, on the dorsal aspect, is a rough surface for the attachment of the Extensor carpi radialis brevior. The carpal, articular facet is concave behind, flat in front, and articulates with the *os magnum*. On the radial side is a smooth, concave facet, for articulation with the second metacarpal bone, and on the ulnar side two small, oval facets, for articulation with the fourth metacarpal.

The side to which this bone belongs is easily recognized by the styloid process on the radial side of its base. With the palmar surface uppermost and the base toward the student, this process points toward the side to which the bone belongs.
Attachment of Muscles.—To six: Extensor carpi radialis brevior, Flexor carpi radialis, Adductor transversus pollicis, Adductor obliquus pollicis, and Second and Third dorsal interosseous.

The Metacarpal Bone of the Ring Finger (os metacarpale IV) (Fig. 150) is shorter and smaller than the preceding, and its base small and quadrilateral; the carpal surface of the base presenting two facets, a large one externally, for articulation with the unciform, and a small one internally, for the os magnum. On the radial side are two oval facets, for articulation with the third metacarpal bone; and on the ulnar side a single concave facet, for the fifth metacarpal.

If this bone is placed with the base toward the student and the palmar surface upward, the radial side of the base, which has two facets for articulation with the third metacarpal bone, will be on the side to which it belongs. If, as sometimes happens in badly marked bones, one of these facets is indistinguishable, the side may be known by selecting the surface on which the larger articular facet is present. This facet is for the fifth metacarpal bone, and would therefore be situated on the ulnar side—that is, the one to which the bone does not belong.

Attachment of Muscles.—To three: the Third and Fourth dorsal and Second palmar interosseous.

The Metacarpal Bone of the Little Finger (os metacarpale V) (Fig. 151) presents on its base one facet, which is concavo-convex, and which articulates with the unciform bone, and one lateral, articular facet, which articulates with the fourth metacarpal bone. On its ulnar side is a prominent tubercle, for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle; the inner division is smooth and covered by the Extensor tendons of the little finger.

If this bone is placed with its base toward the student and its palmar surface upward, the side of the head which has a lateral facet will be that to which the bone belongs.

Attachment of Muscles.—To five: the Extensor carpi ulnaris, Flexor carpi ulnaris, Flexor ossis metacarpi minimi digiti, Fourth dorsal, and Third palmar interosseous.
Articulations.—Besides the phalangeal articulations, the first metacarpal bone articulates with the trapezium; the second with the trapezium, trapezoid, os magnum, and third metacarpal bones; the third with the os magnum and second and fourth metacarpal bones; the fourth with the os magnum, unciform, and third and fifth metacarpal bones; and the fifth with the unciform and fourth metacarpal.

The first has no lateral facets on its carpal extremity; the second has no lateral facet on its radial side, but one on its ulnar side; the third has one on its radial and two on its ulnar side; the fourth has two on its radial and one on its ulnar side; and the fifth has only one on its radial side.

The Phalanges of the Hand (Phalanges Digitorum Manus).

The phalanges (internodia) are the bones of the fingers; they are fourteen in number, three for each finger, and two for the thumb. In numbering them the proximal bone is designated as the first phalanx (phalanx I). They are long bones, and present for examination a shaft and two extremities. The shaft (corpus phalangis) tapers from above downward, is convex posteriorly, concave in front from above downward, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. A nutrient foramen on the palmar surface leads into a nutrient canal which runs toward the periphery (distalward). The metacarpal extremity or base (basis phalangis) of each phalanx in the first row presents an oval, concave, articular surface, broader from side to side than from before backward; and the same extremity in the other two rows, a double concavity, separated by a longitudinal median ridge, extending from before backward. The distal extremity of the first phalanx of the thumb and of the first and second phalanx of each of the fingers is smaller than the base, and terminates in two small, lateral condyles, separated by a slight groove (trochlea phalangis); the articular surface being prolonged farther forward on the palmar than on the dorsal surface, especially in the first row.

The Ungual Phalanges (distal) are convex on their dorsal, flat on their palmar, surfaces; they are recognized by their small size and by a roughened, elevated surface of a horseshoe form on the palmar aspect of their ungual extremity (tuberositas ungualicularis), which serves to support the sensitive pulp of the finger.

Articulations.—The first row, with the metacarpal bones and the second row of phalanges; the second row, with the first and third; the third, with the second row.

Attachment of Muscles.—To the base of the first phalanx of the thumb, five muscles: the Extensor brevis pollicis, Flexor brevis pollicis, Abductor pollicis, Adductor transversus and Obliquus pollicis. To the second phalanx, two: the Flexor longus pollicis and the Extensor longus pollicis. To the base of the first phalanx of the index finger, the First dorsal and the First palmar interosseous; to that of the middle finger, the Second and Third dorsal interosseous; to that of the ring finger, the Fourth dorsal and the Second palmar interosseous; and to that of the little finger, the Third palmar interosseous, the Flexor brevis minimi digitii, and Abductor minimi digitii. To the second phalanges, the Extensor sublimis digitorum, Extensor communis digitorum, and, in addition, the Extensor indicis to the index finger, the Extensor minimi digitii to the little finger. To the third phalanges, the Flexor profundus digitorum and Extensor communis digitorum.

Surface Form.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, due to the tuberosity of the scaphoid and the ridge on the trapezium; the other, on the ulnar side, caused by the pisiform bone. The tubercle of the scaphoid is to be felt just below and in front of the apex of the styloid process of the radius. It is best perceived by extending the hand on the forearm. Immediately below is to be felt another prominence, better marked than the tubercle; this is the ridge on the trapezium which gives attachment to some of the short muscles of the thumb. On the inner side of the front of
the wrist the pisiform bone is to be felt, forming a small but prominent projection in this situation. It is some distance below the styloid process of the ulna, and may be said to be just below the level of the styloid process of the radius. The rest of the front of the carpus is covered by tendons and the annular ligament, and entirely concealed, with the exception of the hooked process of the unciform, which can only be made out with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that none of the posterior surfaces of the bones are to be felt, with the exception of the unciform on the inner side. Below the carpus the dorsal surfaces of the metacarpal bones, except the fifth, are covered by tendons, and are scarcely visible except in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and is plainly to be perceived and felt. In addition to this, slightly external to the middle line of the hand, is a prominence, frequently well marked, but occasionally indistinct, formed by the base of the metacarpal of the middle finger. The heads of the metacarpal bones are plainly to be felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpal bones on to their anterior surfaces, so that the head of these bones form the prominence of the knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges are to be plainly felt: they form the joints of the fingers. When the digits are bent the proximal phalanges of the joints form prominences, which in the joint between the first and second phalanges is slightly hollowed, in accordance with the grooved shape of their articular surfaces, whilst at the last row the prominence is flattened and square-shaped. In the palm of the hand the four inner metacarpal bones are covered by muscles, tendons, and the palmar fascia, and no part of them but their heads is to be distinguished. With regard to the thumb, on the dorsal aspect the base of the metacarpal bone forms a prominence below the styloid process of the radius; the shaft is to be felt, covered by tendons, terminating at its head in a flattened prominence, in front of which can be felt the sesamoid bones.

Surgical Anatomy.—The carpal bones are not very liable to fracture, except from extreme violence, when the parts may be so comminuted as to necessitate amputation. Occasionally they are the seat of tuberculous disease. The metacarpal bones and the phalanges are not unfrequently broken by direct violence. The first metacarpal bone is the one most commonly fractured; then the second, the fourth, and the fifth, the third being the one least frequently broken. There are two diseases of the metacarpal bones and phalanges which require special mention on account of the frequency of their occurrence. One is tuberculous dactylitis, consisting in a deposit of tuberculous material in the medullary canal, expanding the bone, with subsequent caseation and resulting necrosis. The other is chondroma, which is perhaps more frequently found in connection with the metacarpal bones and phalanges than with any other bones. When chondromatous growth takes place there are usually multiple tumors, and they may spring either from the medullary canal or from the periosteum.

Development of the Bones of the Hand.

The Carpal Bones are each developed by a single centre. At birth they are all cartilaginous. Ossification proceeds in the following order (Fig. 152): In the os magnum and unciform an ossific point appears during the first year, the former preceding the latter; in the cuneiform, at the third year; in the trapezium and semilunar, at the fifth year, the former preceding the latter; in the scaphoid, at the sixth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

Occasionally an additional bone, the os centrale, is found in the carpus, lying between the scaphoid, trapezoid, and os magnum. During the second month of fetal life it is represented by a small cartilaginous nodule, which, however, fuses with the cartilaginous scaphoid about the third month. Sometimes the styloid process of the third metacarpal is detached and forms an additional ossicle.

The Metacarpal Bones are each developed by two centres: one for the shaft and one for the digital extremity for the four inner metacarpal bones; one for the shaft and one for the base for the metacarpal bone of the thumb, which in this
respect resembles the phalanges. Ossification commences in the centre of the shaft about the eighth or ninth week, and gradually proceeds to either end of the bone: about the third year the digital extremities of the four inner metacarpal bones and the base of the first metacarpal begin to ossify, and they unite about the twentieth year.

The phalanges are each developed by two centres; one for the shaft and one for the base. Ossification commences in the shaft, in all three rows, at about the eighth week, and gradually involves the whole of the bone excepting the upper extremity. Ossification of the base commences in the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united, in each row, between the eighteenth and twentieth years.

In the ungual phalanges the centre for the shaft appears at the distal extremity of the phalanx, instead of at the middle of the shaft, as is the case with the other phalanges.

THE LOWER EXTREMITY.

The bones of the lower extremity consist of those of the pelvic girdle, of the thigh, of the leg, and of the foot.

1 Allan Thomson has demonstrated the fact that the first metacarpal bone is often developed from three centres; that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis, visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone.—Journal of Anatomy, 1869.
THE PELVIC GIRDLE.

The pelvic girdle consists of a single bone, the os innominatum, by which the thigh is connected to the trunk.

The Os Innominatum, called also Os Coxae, Hip Bone, Haunch Bone, the Nameless Bone (Figs. 153, 154).

The os innominatum (in, not; nomino, I name) is so called from bearing no resemblance to any known object. It is a large, irregularly shaped, flat bone, constricted in the centre and expanded above and below. With its fellow of the opposite side it forms the sides and anterior wall of the pelvic cavity. In young subjects it consists of three separate parts, which meet and form the large, cup-like cavity, the acetabulum, situated near the middle of the outer surface of the bone; and, although in the adult these have become united, it is usual to describe the bone as divisible into three portions—the ilium, the ischium, and the pubis.

The ilium, so called from its supporting the flank (ilio or ilium, the flank), is the superior, broad, and expanded portion which runs upward from the acetabulum and forms the prominence of the hip.

The ischium (ischiou, the hip) is the inferior and strongest portion of the bone; it proceeds downward from the acetabulum, expands into a large tuberosity, and then, curving forward, forms, with the descending ramus of the os pubis, a large aperture, the obturator foramen.

The os pubis is that portion which extends inward and downward from the acetabulum to articulate in the middle line with the bone of the opposite side: it forms the front of the pelvis, supports the external organs of generation, and has received its name from the skin over it being covered with hair (pubes).

The Ilium (os ilium).—The lower or constricted part of the ilium is thick, though narrower than the expanded portion. It aids in the formation of the acetabulum and is called the body (corpus ossis ilium). The broad expanded portion of the ilium is thin in many places. It is called the ala (ala ossis ilium). The ilium presents for examination two surfaces, an external and an internal; a crest, and two borders, an anterior and a posterior.

External Surface or Dorsum of the Ilium (Fig. 153).—The posterior part of this surface is directed backward and outward; its front part, downward and outward. It is smooth, convex in front, deeply concave behind; bounded above by the crest, below by the upper border of the acetabulum; in front and behind by the anterior and posterior borders. This surface is crossed in an arched direction by three semicircular lines—the superior, middle, and inferior curved lines. The superior curved line, or the posterior gluteal line (linea glutaea posterior), the shortest of the three, commences at the crest, about two inches in front of its posterior extremity; it is at first distinctly marked, but as it passes downward and backward to the upper part of the great sacro-sciatic notch, where it terminates, it becomes less marked, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and affords attachment to part of the Gluteus maximus; the lower part is smooth and has no muscular fibres attached to it. The middle curved line, or the anterior gluteal line (linea glutaea anterior), the longest, of the three, commences at the crest, about an inch behind its anterior extremity, and, taking a curved direction downward and backward, terminates at the upper part of the great sacro-sciatic notch. The space between the superior and middle curved lines and the crest is concave, and affords attachment to the Gluteus medius muscle. Near the central part of this line may often be observed the orifice of a nutrient foramen. The inferior
curved or inferior gluteal line (linea glutaea inferior), the least distinct of the three, commences in front at the notch on the anterior border, and, taking a curved direction backward and downward, terminates at the middle of the great sacro-sciatic notch. The surface of bone included between the middle and inferior curved lines is concave from above downward, convex from before backward, and affords attachment to the Gluteus minimus muscle. Beneath the inferior curved line, and corresponding to the upper part of the acetabulum, is a roughened surface (sometimes a depression), to which is attached the reflected tendon of the Rectus femoris muscle.

**Internal Surface.**—The internal surface (Fig. 154) of the ilium is bounded above by the crest; below it is continuous with the pelvic surface of the os pubis and ischium, a faint line only indicating the place of union; and before and behind it
is bounded by the anterior and posterior borders. It presents a large, smooth, concave surface, called the iliac fossa, or venter ili (fossa iliaca), which lodges the Iliacus muscle, and presents at its lower part the orifice of a nutrient canal (foramen nutricium); and below this a smooth, rounded border, the ilio-pectineal line or the linea ilio-pectinea (linea arcuata), which separates the iliac fossa from that portion of the internal surface which enters into the formation of the true pelvis, and which gives attachment to part of the Obturator internus muscle. Behind the iliac fossa is a rough surface divided into two portions, an anterior and a posterior. The anterior or auricular surface (facies auricularis), so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a surface of similar shape on the side of the sacrum. The posterior portion (tuberositas iliaca) is rough, for the attachment of the posterior sacro-iliac ligaments and for a part of the origin of the Erector and Multifidus

Fig. 154.—Right os innominatum. Internal surface.
spine. In many bones a furrow exists in front, under and behind the auricular surface. This furrow is the paraglenoid sulcus (sulcus paraglenoidalis), and it affords attachment to the sacro-sciatic ligaments.

The Crest of the Ilium (crista iliaca).—The crest of the ilium is convex in its general outline and sinuously curved, being concave inward in front, concave outward behind. It is longer in the female than in the male, very thick behind, and thinner at the centre than at the extremities. It terminates at either end in a prominent eminence, the anterior superior and posterior superior spinous process (spina iliaca anterior superior et spina iliaca posterior superior). The surface of the crest is broad, and divided into an external lip (labium externum), an internal lip (labium internum), and an intermediate space (linea intermedia). About two inches behind the anterior superior spinous process there is a prominent tubercle on the outer lip. To the external lip is attached the Tensor fasciae femoris, Obliquus externus abdominis, and Latissimus dorsi, and along its whole length, the fascia lata; to the space between the lips, the Internal oblique; to the internal lip, the Transversalis, Quadratus lumborum, and Erector spinae, the Iliacus, and the fascia iliaca.

Anterior Border.—The anterior border of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the anterior superior spinous process of the ilium (spina iliaca anterior superior), the outer border of which gives attachment to the fascia lata and the origin of the Tensor fasciae femoris (tensor vaginæ femoris); its inner border, to the Iliacus; while its extremity affords attachment to Poupart’s ligament and the origin of the Sartorius. Beneath this eminence is a notch which gives attachment to the Sartorius muscle, and across which passes the external cutaneous nerve. Below the notch is the anterior inferior spinous process (spina iliaca anterior inferior), which terminates in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris muscle and the ilio-femoral ligament. On the inner side of the anterior inferior spinous process is a broad, shallow groove, over which passes the Ilio-psaas muscle. This groove is bounded internally by an eminence, the ilio-pectineal eminence (eminentia iliopectinea), which marks the point of union of the ilium and os pubis.

Posterior Border.—The posterior border of the ilium, shorter than the anterior, also presents two projections separated by a notch, the posterior superior spinous process (spina iliaca posterior superior) and the posterior inferior spinous process (spina iliaca posterior inferior). The former corresponds with that portion of the inner surface of the ilium which serves for the attachment of the oblique portion of the sacro-iliac ligaments and the Multifidus spine muscle; the latter, to the auricular portion which articulates with the sacrum. Below the posterior inferior spinous process is a deep notch, the great sciatic, ilio-sciatic, or the great sacro-sciatic notch (inieitura ischiadica major).

The Ischium (os ischii).—The ischium forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion—the body; a large, rough eminence, on which the trunk rests in sitting—the tuberosity; and a thin part which passes forward and slightly upward—the ramus.

The Body (corpus ossis ischii).—The body, somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The external surface corresponds to that portion of the acetabulum formed by the ischium; it is smooth and concave, and forms a little more than two-fifths of the acetabular cavity; its outer margin is bounded by a prominent rim or lip, the external border, to which the cotyloid fibro-cartilage is attached. Below the acetabulum, between it and the tuberosity, is a deep groove, along which the tendon of the Obturator externus muscle runs
as it passes outward to be inserted into the digital fossa of the femur. The internal surface is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity. This surface is perforated by two or three large, vascular foramina, and affords attachment to part of the Obturator internus muscle. The posterior surface is quadrilateral in form, broad and smooth. Below, where it joins the tuberosity, it presents a groove, the obturator groove (sulcus obturatorius), continuous with that on the external surface, for the tendon of the Obturator externus muscle. The lower edge of this groove is formed by the tuberosity of the ischium, and affords attachment to the Gemellus inferior muscle. This surface is limited, externally, by the margin of the acetabulum; behind, by the posterior border; it supports the Pyriformis, the two Gemelli, and the Obturator internus muscles in their passage outward to the great trochanter.

The external border forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid fibro-cartilage. The internal border is thin, and forms the outer circumference of the obturator foramen. The posterior border of the body of the ischium presents, a little below the centre, a thin and pointed, triangular eminence, the spine of the ischium (spina ischiadica), more or less elongated in different subjects; its external surface gives attachment to the Gemellus superior, its internal surface to the Coccygeus and Levator ani; whilst to the pointed extremity is connected the lesser sacro-sciatic ligament. Above the spine is a notch of large size, the great sacro-sciatic notch (incisura ischiadica major), converted into a foramen, the great sacro-sciatic foramen (foramen ischiadicum majus), by the lesser sacro-sciatic ligament; it transmits the Pyriformis muscle, the gluteal vessels, and superior and inferior gluteal nerves; the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and the nerves to the Obturator internus and Quadratus femoris. Of these, the gluteal vessels and superior gluteal nerve pass out above the Pyriformis muscle, the other structures, below it. Below the spine is a smaller notch, the lesser sacro-sciatic notch (incisura ischiadica minor); it is smooth, coated in the recent state with cartilage, the surface of which presents two or three ridges corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen, the lesser sacro-sciatic foramen (foramen ischiadicum minus), by the sacro-sciatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve. The Tuberosity of the Ischium (tuber ischiadicum).—The tuberosity of the ischium is the portion of bone between the body and the ascending ramus. Some anatomists name this portion of bone the descending or superior ramus (ramus superior ossis ischii), and restrict the term tuberosity to the surface of the bone which is rough, and is directed backward and outward. The tuberosity presents for examination three surfaces: external, internal, and posterior. The external surface is quadrilateral in shape, and rough for the attachment of muscles. It is bounded above by the groove for the tendon of the Obturator externus; in front it is limited by the posterior margin of the obturator foramen, and below it is continuous with the ramus of the bone; behind, it is bounded by a prominent margin which separates it from the posterior surface. In front of this margin the surface gives attachment to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus. The lower part of the surface gives origin to part of the Adductor magnus. The internal surface forms part of the bony wall of the true pelvis. In front it is limited by the posterior margin of the obturator foramen. Behind, it is bounded by a sharp ridge, for the attachment of a falciform prolongation of the great sacro-sciatic ligament; it sometimes presents a groove on the inner side of this ridge for the lodgement of the internal pudic vessels and nerve; and, more anteriorly, has
attached the Transversus perinei and Erector penis muscles. The posterior surface is divided into two portions—a lower rough, somewhat triangular part, and an upper smooth, quadrilateral portion. The anterior portion is subdivided by a prominent vertical ridge, passing from base to apex, into two parts; the outer one gives attachment to the Adductor magnus; the inner to the great sacrosciatic ligament. The upper portion is subdivided into two facets by an oblique ridge which runs downward and outward; from the upper and outer facet arises the Semimembranosus; from the lower and inner, the Biceps and Semitendinosus.

The Ramus or Inferior Ramus or Ascending Ramus of the Ischium (ramus inferior ossis ischii).—The ramus is the thin, flattened part of the ischium which ascends from the tuberosity upward and inward, and joins the descending ramus of the os pubis, their point of junction being indicated in the adult by a rough line. The outer surface of the ramus is rough, for the attachment of the Obturator externus muscle, and also some fibres of the Adductor magnus; its inner surface forms part of the anterior wall of the pelvis. Its inner border is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the os pubis: to the outer one is attached the deep layer of the superficial perineal fascia, and to the inner, the superficial layer of the triangular ligament of the urethra. If these two ridges are traced downward, they will be found to join with each other just behind the point of origin of the Transversus perinei muscle; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, is attached the Transversus perinei muscle, and in front of this a portion of the crus penis vel clitoridis and the Erector penis vel clitoridis muscle. Its outer border is thin and sharp, and forms part of the inner margin of the obturator foramen.

The Pubis (os pubis).—The os pubis forms the anterior part of the os innominatum, and, with the bone of the opposite side, forms the front boundary of the true pelvic cavity. It is divisible into a body, an ascending and a descending ramus.

The Body (corpus ossis pubis).—The body is the broad portion of bone formed by the junction of the two rami. It is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The anterior surface is rough, directed downward and outward, and serves for the attachment of various muscles. To the upper and inner angle, immediately below the crest, is attached the Adductor longus; lower down, from without inward, are attached the Obturator externus, the Adductor brevis, and the upper part of the Gracilis. The posterior surface, convex from above downward, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives attachment to the Levator ani, Obturator internus, a few muscular fibres prolonged from the bladder, and the pubo-prostatic ligaments. The upper border presents for examination a prominent tubercle, which projects forward and is called the spine (tuberculum pubicum); to it are attached the outer pillar of the external abdominal ring and Poupart's ligament. Passing upward and outward from this is a prominent ridge, forming part of the ilio-pectineal line (linea arcuata), and called the pecten ossis pubis. It marks the brim of the true pelvis: to it are attached a portion of the conjoined tendon of the Internal oblique and Transversalis muscles, Gimbernat's ligament, and the triangular fascia of the abdomen. Internal to the spine of the os pubis is the crest, which extends from this process to the inner extremity of the bone. It affords attachment, anteriorly, to the conjoined tendon of the Internal oblique and Transversalis; and posteriorly, to the Rectus and Pyramidalis muscles. The point of junction of the crest with the inner border of the bone (symphysis) is called the angle; to it, as well as to the symphysis, is attached the internal pillar of the external abdominal ring. The
internal border is articular; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, placed between it and the central fibro-cartilage. The outer border presents a sharp margin, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The Ascending or Superior Ramus of the Pubis (ramus superior ossis pubis).—The ascending or superior ramus extends from the body to the point of junction of the os pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination a superior, inferior, and posterior surface, and an outer extremity. The superior surface presents a continuation of the ilio-pectineal line, already mentioned as commencing at the pubic spine. In front of this ridge the surface of bone is triangular in form, wider externally than internally, smooth, and is covered by the Pectineus muscle. The surface is bounded externally by a rough eminence, the ilio-pectineal eminence (eminencia ilipectinae), which serves to indicate the point of junction of the ilium and os pubis, and gives attachment to the Psoas parvus, when this muscle is present. The triangular surface is bounded below by a prominent ridge, the obturator crest (crista obturatoria), which extends from the cotyloid notch to the spine of the os pubis. The inferior surface forms the upper boundary of the obturator foramen, and presents externally a broad and deep oblique groove, the obturator groove (sulcus obturatorius), for the passage of the obturator vessels and nerve; and internally a sharp margin which forms part of the circumference of the obturator foramen, and to which the obturator membrane is attached. The posterior surface forms part of the anterior boundary of the true pelvis. It is smooth, convex from above downward, and affords attachment to some fibres of the Obturator internus. The outer extremity, the thickest part of the ramus, forms one-fifth of the cavity of the acetabulum.

The Descending or Inferior Ramus of the Pubis (ramus inferior ossis pubis).—The descending or inferior ramus of the os pubis is thin and flattened. It passes outward and downward, becoming narrower as it descends, and joins with the ramus of the ischium. Its anterior surface is rough, for the attachment of muscles—the Gracilis along its inner border; a portion of the Obturator externus where it enters into the formation of the foramen of that name; and between these two muscles the Adductores brevis and magnus from within outward. The posterior surface is smooth, and gives attachment to the Obturator internus, and, close to the inner margin, to the Compressor urethrae. The inner border is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downward, and are continuous with similar ridges on the ascending ramus of the ischium; to the external one is attached the deep layer of the superficial perineal fascia, and to the internal one the superficial layer of the triangular ligament of the urethra. The outer border is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The Cotyloid Cavity or Acetabulum.—The cotyloid cavity, or acetabulum, is a deep, cup-shaped, hemispherical depression, directed downward, outward, and forward; formed internally by the os pubis, above by the ilium, behind and below by the ischium, a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent, uneven rim, which is thick and strong above, and serves for the attachment of the cotyloid ligament, which contracts its orifice and deepens the surface for articulation. It presents below a deep notch, the cotyloid notch (incisura acetabuli), which is continuous with a circular depression, the fossa of the acetabulum (fossa acetabuli), at the bottom of the cavity: this depression is
perforated by numerous apertures, lodges a mass of fat, and its margins, as well as those of the notch, serve for the attachment of the ligamentum teres. In front, above and behind the fossa acetabuli, is a concave rim of bone (facies lunata). The cotyloid notch is converted, in the natural state, into a foramen by a dense ligamentous band which passes across it. Through this foramen the nutrient vessels and nerves enter the joint.

The Obturator or Thyroid Foramen (foramen obturatum).—The obturator or thyroid foramen is a large aperture situated between the ischium and os pubis. In the male it is large, of an oval form, its longest diameter being obliquely from before backward; in the female it is smaller and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached, and presents, anteriorly, a deep groove, the obturator groove (sulcus obturatorius), which runs from the pelvis obliquely inward and downward. This groove is converted into a foramen by the obturator membrane, and transmits the obturator vessels and nerve.

Structure.—This bone consists of much cancellous tissue, especially where it is thick, enclosed between two layers of dense, compact tissue. In the thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, it is usually semitransparent, and composed entirely of compact tissue.

Development (Fig. 155).—By eight centres: three primary—one for the ilium, one for the ischium, and one for the os pubis; and five secondary—one for the crest of the ilium, one for the anterior inferior spinous process (said to occur more frequently in the male than in the female), one for the tuberosity of the ischium, one for the symphysis pubis (more frequent in the female than the male), and one or more for the Y-shaped piece at the bottom of the acetabulum. These various centres appear in the following order: First, in the ilium, at the lower part of
the bone, immediately above the sciatic notch, at about the eighth or ninth week; secondly, in the body of the ischium, at about the third month of fetal life; thirdly, in the body of the os pubis, between the fourth and fifth months. At birth the three primary centres are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, and the rami of the ischium and pubes being still cartilaginous. At about the seventh or eighth year the rami of the os pubis and ischium are almost completely united by bone. About the thirteenth or fourteenth year the three divisions of the bone have extended their growth into the bottom of the acetabulum, being separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the os acetabuli, appears about the age of twelve, between the ilium and os pubis, and fuses with them about the age of eighteen. It forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the os pubis to the ischium, through the intervention of this Y-shaped portion. At about the age of puberty ossification takes place in each of the remaining portions, and they become joined to the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic and ischial spines

Articulations.—With its fellow of the opposite side, the sacrum, and femur.

Attachment of Muscles.—To the ilium, sixteen. To the outer lip of the crest, the Tensor vaginae femoris, Obliquus externus abdominis, and Latissimus dorsi; to the internal lip, the Iliacus, Transversalis, Quadratus lumborum, and Erector spine; to the interspace between the lips, the Obliquus internus. To the outer surface of the ilium, the Gluteus maximus, Gluteus medius, Glutens minimus, reflected tendon of the Rectus; to the upper part of the great sacro-sciatic notch, a portion of the Pyriformis; to the internal surface, the Iliacus; to that portion of the internal surface below the linea ilio-pectinea, the Obturator internus to the internal surface of the posterior superior spine, and the Multifidus spine; to the anterior border, the Sartorius and straight tendon of the Rectus. To the ischium, thirteen. To the outer surface of the ramus, the Obturator externus and Adductor magnus; to the internal surface, the Obturator internus and Erector penis. To the spine, the Gemellus superior, Levator ani, and Coccygens. To the tuberosity, the Biceps, Semitendinosus, Semimembranosus, Quadratus femoris, Adductor magnus, Gemellus inferior, Transversus perinæi, Erector penis. To the pubis, sixteen: Obliquus externus, Obliquus internus, Transversalis, Rectus, Pyramidalis, Psoas parvus, Pectineus, Adductor magnus, Adductor longus, Adductor brevis, Gracilis, Obturator externus and internus, Levator ani, Compressor urethre, and occasionally a few fibres of the Accelarator urine.

The Pelvis (Figs. 156, 157).

The pelvis, so called from its resemblance to a basin (L. pelvis), is stronger and more massively constructed than either the cranial or thoracic cavity; it is a bony ring, interposed between the lower end of the spine, which it supports, and the lower extremities, upon which its rests. It is composed of four bones: the two ossa innominata, which bound it on either side and in front, and the sacrum and coccyx, which complete it behind. The pelvis is divided by an oblique plane passing through the prominence of the sacrum, the linea ilio-pectinea, and the upper margin of the symphysis pubis into the false and true pelvis.

The False Pelvis (pelvis major).—The false pelvis is the expanded portion of the pelvic cavity which is situated above this plane. It is bounded on each side by the osa ili; in front it is incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch:.. This
broad, shallow cavity is fitted to support the intestines and to transmit part of their weight to the anterior wall of the abdomen, and is, in fact, really a portion of the abdominal cavity. The term false pelvis is incorrect, and this space ought

more properly to be regarded as part of the hypogastric and iliac regions of the abdomen.

**The True Pelvis** (*pelvis minor*).—The true pelvis is that part of the pelvic cavity which is situated beneath the plane. It is smaller than the false pelvis,

but its walls are more perfect. For convenience of description it is divided into a **superior circumference** or **inlet**, an **inferior circumference** or **outlet**, and a **cavity**.
The Superior Circumference or Inlet (apertura pelvis superior).—The superior circumference forms the brim of the pelvis, the included space being called the inlet. It is formed by the linea ilipectinea, completed in front by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacro-vertebral angle. The brim of the pelvis is the name often given to the margin of the inlet. The inlet of the pelvis is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forward of the promontory of the sacrum. It has three principal diameters: antero-posterior (sacro-pubic), transverse, and oblique. The antero-posterior or conjugate diameter (conjugata) extends from the sacro-vertebral angle to the symphysis pubis. The anatomical conjugate (conjugata anatomica) is the distance between the sacro-vertebral angle and the top of the symphysis pubis. Its average measurement is four inches in the male and four and three-fifths inches in the female. The true, available, or obstetric conjugate (conjugata gynaecologica) is the distance between the sacro-vertebral angle and the nearest point upon the symphysis. This point is a little behind and below the upper margin (Webster). The average distance in women is four and three-eighths inches. The diagonal conjugate (diagonale conjugata) is measured from the sacro-vertebral angle to the subpubic ligament. The distance exceeds the true conjugate by one-half or two-thirds of an inch. The transverse diameter (diameter transversa) extends across the greatest width of the inlet, from the middle of the brim on one side to the same point on the opposite; its average measurement is five inches in the male, five and one-fourth inches in the female. The oblique diameter (diameter obliqua) extends from the margin of the pelvis, corresponding to the ilio-pectineal eminence on one side, to the sacro-iliac articulation on the opposite side; its average measurement is four and a quarter inches in the male and five in the female. The oblique diameters are named right or left oblique, according to the sacro-iliac joint from which the measurement is taken.

The Cavity.—The cavity of the true pelvis is bounded in front by the symphysis pubis; behind, by the concavity of the sacrum and coccyx, which, curving forward above and below, contracts the inlet and outlet of the canal; and laterally it is bounded by a broad, smooth, quadrangular surface of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-pectineal line. The cavity is shallow in front, measuring at the symphysis an inch and a half in depth, three inches and a half in the middle, and four inches and a half posteriorly. From this description it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall. This cavity contains, in the recent subject, the rectum, bladder, and part of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacro-coccygeal column; the bladder in front, behind the symphysis pubis. In the female the uterus and vagina occupy the interval between these viscera.

The Lower Circumference or Outlet (apertura pelvis inferior).—The lower circumference of the pelvis is very irregular, and forms what is called the outlet. It is bounded by three prominent eminences: one posterior, formed by the point of the coccyx; and one on each side, the tuberosities of the ischia. These eminences are separated by three notches; one in front, the pubic arch (arcus pubis), formed by the convergence of the rami of the ischia and pubic bones on each side. The other notches, one on each side, are formed by the saerum and coccyx behind, the ischium in front, and the ilium above; they are called the sacro-sciatic notches; in the natural state they are converted into foramina by the lesser and greater sacro-sciatic ligaments. In the recent state, when the ligaments are in situ, the outlet of the pelvis is lozenge-shaped, bounded in front by the subpubic ligament and the rami of the os pubis and ischiium; on each side by the tuber-
osities of the ischia; and behind by the great sacro-sciatic ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The antero-posterior (conjugate) diameter (diameter recta of the outlet) extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three and three-quarter inches in the male and four and one-half inches in the female. The antero-posterior diameter varies with the length of the coccyx, and is capable of increase or diminution on account of the mobility of that bone. During labor the coccyx may be bent back so that the conjugate is increased one inch, or even one and one-fourth inches. The transverse diameter extends from the posterior part of one ischiatic tuberosity to the same point on the opposite side; the average measurement is three and a half inches in the male and four and three-fourths in the female.1

Oblique diameters are not employed, as there are no fixed points from which to measure them.

Position of the Pelvis.—In the erect posture the pelvis is placed obliquely with regard to the trunk of the body: the bony ring, which forms the brim of the true pelvis, is placed so as to form an angle of about 60 to 65 degrees with the ground on which we stand (inclinatio pelvis). The pelvic surface of the symphysis pubis looks upward and backward, the concavity of the sacrum and coccyx downward and forward, the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. In consequence of the obliquity of the pelvis the line of gravity of the head, which passes through the middle of the odontoid process of the axis and through the points of junction of the curves of the vertebral column to the sacro-vertebral angle, descends toward the front of the cavity, so that it bisects a line drawn transversely through the middle of the heads of the thigh bones. And thus the centre of gravity of the head is placed immediately over the heads of the thigh bones on which the trunk is supported.

Axes of the Pelvis (Fig. 158).—The plane of the inlet of the true pelvis will be represented by a line drawn from the base of the sacrum to the upper margin of the symphysis pubis. A line carried at right angles with this at its middle would correspond at one extremity with the umbilicus, and at the other with the middle of the coccyx: the axis of the inlet. The axis of the outlet, produced upward, would touch the base of the sacrum, and is therefore directed downward and forward. The axis of the cavity is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and

---

1 The measurements of the pelvis given above are, I believe, fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken. The accompanying chart has been formulated to show the measurements of the pelvis which are adopted by many obstetricians. —Ed.

### Diameters of the True Pelvis in Woman.

outlet. A knowledge of the direction of these axes serves to explain the course of the foetus in the passage through the pelvis during parturition. It is also important to the surgeon, as indicating the direction of the force required in the removal of calculi from the bladder by the sub-pubic operation, and as determining the direction in which instruments should be used in operations upon the pelvic viscera.

**Differences between the Male and the Female Pelvis.**—The female pelvis, looked at as a whole, is distinguished from the male by the bones being more delicate, by its width being greater and its depth smaller. The whole pelvis is less massive, and its bones are lighter and more slender, and its muscular impressions are slightly marked. The iliac fossae are shallow, and the anterior iliac spines widely separated; hence the greater prominence of the hips. The **inlet** in the female is larger than in the male; it is more nearly circular, and the sacro-vertebral angle projects less forward. The **cavity** is shallower and wider; the sacrum is shorter, wider, and less curved; the obturator foramina are triangular, and smaller in size than in the male. The **outlet** is larger and the coccyx more movable. The spines of the ischia project less inward. The tuberosities of the ischia and the acetabula are wider apart. The **pubic arch** is wider and more rounded than in the male, where it is an angle rather than an arch. In consequence of this the width of the fore part of the pelvic outlet is much increased and the passage of the foetal head facilitated.

The size of the pelvis varies, not only in the two sexes, but also in different members of the same sex. This does not appear to be influenced in any way by

![Fig. 159.—Diameters of the pelvic inlet.](image)

the height of the individual. Women of short stature; as a rule, have broad pelves. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in women of average height and otherwise well formed. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior to the transverse diameter. Thus we may have a pelvis the inlet of which is elliptical either in a transverse or antero-posterior direction; the transverse diameter in the former and the antero-posterior in the latter greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular. The same differences are found in various races. European women are said to have the
most roomy pelves. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelves.

In the fetus and for several years after birth the pelvis is small in proportion to that of the adult. The cavity is deep, and the projection of the sacro-vertebral angle less marked. The generally accepted opinion that the female pelvis does not acquire its sexual characters until after puberty has been shown by recent observations\(^1\) to be erroneous, the characteristic differences between the male and female pelvis being distinctly indicated as early as the fourth month of fetal life. At birth these differences are distinct (Romiti), the female pelvis possessing less straight ilia, a broader subpubic arch, and less height than the male.

**Surface Form.**—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spinous process is easily recognized; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the fold of the groin. In fat subjects its position is marked by an oblique depression amongst the surrounding fat, at the bottom of which the bony process may be felt. Proceeding upward and outward from this process, the crest of the ilium may be traced throughout its whole length, sinuously curved. It is represented, in muscular subjects, on the surface, by a groove or furrow, the iliac furrow, caused by the projection of fleshy fibres of the External oblique muscles of the abdomen; the iliac furrow lies slightly below the level of the crest. It terminates behind in the posterior superior spinous process, the position of which is indicated by a slight depression on a level with the spinous process of the second sacral vertebra. Between the two posterior superior spinous processes, but at a lower level, is to be felt the spinous process of the third sacral vertebra (see page 69). Another part of the bony pelvis easily accessible to touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, is easily felt, as it is then to a great extent uncovered by muscle. Finally, the spine of the os pubis can always be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is nearly in the same horizontal line with the upper edge of the great trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following up the tendon of origin of the Adductor longus muscle.

**Surgical Anatomy.**—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forward, and the obturator foramen diminished in size, narrowed, and turned outward. The

---

iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the ilio-sacral facets turned more outward than normal, while the vertical curve is straightened.

Fractures of the pelvis are divided into fractures of the false pelvis and of the true pelvis. Fractures of the false pelvis vary in extent: a small portion of the iliac crest may be broken or one of the spinous processes may be torn off, and this may be the result of muscular action; or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the true pelvis. Fractures of the true pelvis generally occur through the ascending ramus of the os pubis and the ramus of the ischium, as this is the weakest part of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together, and the bone gives way in the same place from indirect violence. Occasionally the injury may be double, a break occurring on both sides of the body. In fracture of the true pelvis the contained viscera are liable to be damaged: the small intestines, the urethra, the bladder, the rectum, the vagina, and even the uterus, in the female, have all been lacerated by a displaced fragment. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur may be driven inward and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, dispersing the bone into its three anatomical portions.

The sacrum is seldom broken. The cause is direct violence—i.e., blows, kicks, or falls on the part. The lesion may be complicated with injury to the nerves of the sacral plexus, leading to paralysis and loss of sensation in the lower extremity or to incontinence of feces from paralysis of the Sphincter ani.

The pelvic bones often undergo important deformity in rickets, the effect of which in the adult woman may interfere seriously with childbearing. The deformity is due mainly to the weight of the spine and trunk, which presses on the sacro-vertebral angle and greatly increases it, so that the antero-posterior diameter of the pelvis is diminished. But, in addition to this, the weight of the viscera on the venter ili causes those bones to expand and the tuberosities of the ischia to incurve. In osteomalacia also great deformity may occur. The weight of the trunk causes an increase in the sacro-vertebral angle and a lessening of the antero-posterior diameter of the inlet, and at the same time the pressure of the acetabula on the heads of the thigh-bones causes these cavities, with the adjacent bone, to be pushed upward and backward, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a triradiate shape, with the symphysis pubis pushed forward.

THE THIGH.

The thigh is that portion of the lower extremity which is situated between the pelvis and the knee. It consists in the skeleton of a single bone, the femur.

The Femur, or Thigh Bone (Figs. 161, 162).

The femur (femur, the thigh) is the longest, largest, and strongest bone in the skeleton, and almost perfectly cylindrical throughout the greater part of its extent. In the erect posture it is not vertical, being separated from its fellow above by a considerable interval, which corresponds to the entire breadth of the pelvis, but inclining gradually downward and inward, so as to approach its fellow toward its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a shaft and two extremities.

Upper Extremity.—The upper extremity presents for examination a head, a neck, and a great and lesser trochanters.

Head of the Femur (caput femoris).—The head, which is globular, and forms rather more than a hemisphere, is directed upward, inward, and a little

---

2 In a man six feet high it measures eighteen inches—one-fourth of the whole body.
forward, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the recent state, except at a little behind and below its centre, where is an ovoid depression (fovea capitis femoris), for the attachment for the Ligamentum teres.

The Neck of the Femur (collum femoris).—The neck is a flattened pyramidal process of bone which connects the head with the shaft. It varies in length and obliquity at various periods in life and under different circumstances. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the shaft. In the adult it forms an angle of about 130 degrees with the shaft, but varies in inverse proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh bone forms more nearly a right angle with the shaft than it does in man. It has been stated that the angle diminishes in old age and the direction of the neck becomes horizontal, but this statement is founded on insufficient evidence. Sir George Humphry states that the angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age. He further states that the angle varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide. 1 The neck is flattened from before backward, contracted in the middle, and broader at its outer extremity, where it is connected with the shaft, than at its summit, where it is attached to the head. The vertical diameter of the outer half is increased by the thickening of the lower edge, which slopes downward to join the shaft at the lesser trochanter, so that the outer half of the neck is flattened from before backward, and its vertical diameter measures one-third more than the antero-posterior. The inner half is smaller and of a more circular shape. The anterior surface of the neck is perforated by numerous vascular foramina. The posterior surface is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior intertrochanteric line. The superior border is short and
thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The inferior border, long and narrow, curves a little backward, to terminate at the lesser trochanter.

The Trochanters.—The trochanters (τροχάντερα, to run or roll) are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, the greater and the lesser.

The great trochanter (trochanter major) is a large, irregular, quadrilateral eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outward and backward, and in the adult is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The external surface, quadrilateral in form, is broad, rough, convex, and marked by a prominent diagonal impression, which extends from the posterior superior to the anterior inferior angle, and serves for the attachment of the tendon of the Gluteus medius. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between that tendon and the bone. Below and behind the diagonal line is a smooth, triangular surface, over which the tendon of the Gluteus maximus muscle plays, a bursa being interposed. The internal surface is of much less extent than the external, and presents at its base a deep depression, the digital or trochanteric fossa (fossa trochanterica), for the attachment of the tendon of the Obturator externus muscle: above and in front of this an impression for the attachment of the Obturator internus and Gemelli. The superior border is free; it is thick and irregular, and marked near the centre by an impression for the attachment of the Pyriformis. The inferior border corresponds to the point of junction of the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives attachment to the upper part of the Vastus externus muscle. The anterior border is prominent, somewhat irregular, as well as the surface of bone immediately below it; it affords attachment at its outer part to the Gluteus minimus. The posterior border is very prominent, and appears as a free, rounded edge, which forms the back part of the digital fossa.

The lesser trochanter (trochanter minor) is a conical eminence which varies in size in different subjects; it projects from the lower and back parts of the base of the neck. Its base is triangular, and connected with the adjacent parts of the bone by three well-marked borders: two of these are above—the internal border, continuous with the lower border of the neck, the external border with the posterior intertrochanteric line—while the inferior border is continuous with the middle division of the linea aspera. Its summit, which is directed inward and backward, is rough, and gives insertion to the tendon of the Ilio-psoas. The Iliacus is also inserted into the shaft below the lesser trochanter between the Vastus internus in front and the Pectineus behind.

A well-marked prominence of variable size, which projects from the upper and front part of the neck at its junction with the great trochanter, is called the tubercle of the femur; it is the point of meeting of five muscles: the Gluteus minimus externally, the Vastus externus below, and the tendon of the Obturator internus and Gemelli above. Running obliquely downward and inward from the tubercle is the spiral line of the femur, or anterior intertrochanteric line (linea intertrochanterica); it winds round the inner side of the shaft, below the lesser trochanter, and terminates in the linea aspera, about two inches below this eminence. Its upper half is rough, and affords attachment to the ilio-femoral ligament of the hip-joint; its lower half is less prominent, and gives attachment to the upper part of the Vastus internus. Running obliquely downward and inward from the summit of the great trochanter on the posterior surface of the neck is a very prominent, well-marked ridge, the posterior intertrochanteric line (crista intertrochanterica). Its upper half forms the posterior border of the great trochanter, and its lower
half runs downward and inward to the upper and back part of the lesser trochanter. A slight ridge sometimes commences about the middle of the posterior intertrochanteric line, and passes vertically downward for about two inches along the back part of the shaft: it is called the *linea quadrati*, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus muscles.

The Shaft of the Femur (corpus femoris).—The shaft, almost cylindrical in form, is a little broader above than in the centre, and somewhat flattened below, from before backward. It is slightly arched, so as to be convex in front and concave behind, where it is strengthened by a prominent longitudinal ridge, the *linea aspera*. It presents for examination three borders, separating three surfaces. Of the three borders, one, the *linea aspera*, is posterior; the other two are placed laterally.

The Linea Aspera.—The *linea aspera* (Fig. 162) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an *external lip* (labium laterale), an *internal lip* (labium mediale), and a rough intermediate space. Above, this crest is prolonged by three ridges. The most *external ridge* is very rough, and is continued almost vertically upward to the base of the great trochanter. It is sometimes termed the *gluteal ridge* (tuberositas glutea), and gives attachment to part of the Gluteus maximus muscle; its upper part is sometimes elongated into a roughened crest, on which is a more or less well-marked, rounded tubercle, a *rudimental third trochanter* (trochanter tertius). The *middle ridge* (linea pectinea), the least dis-

---

1 Generally there is merely a slight thickening about the centre of the intertrochanteric line, marking the point of attachment of the Quadratus femoris. This is termed by some anatomists the *tubercle of the Quadratus*. 
tinct, is continued to the base of the trochanter minor, and the **internal ridge** is lost above in the spiral line of the femur. Below, the linea aspera is prolonged by two ridges, which pass to the condyles and enclose between them a triangular space, the **popliteal surface** (*planum popliteum*), upon which rests the popliteal artery. Of these two ridges, the **outer** one is the more prominent, and descends to the summit of the outer condyle. The **inner** one is less marked, especially at its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the **adductor tubercle**, which affords attachment to the tendon of the Adductor magnus. To the inner lip of the linea aspera and its inner prolongation above and below is attached the Vastus internus, and to the outer lip and its outer prolongation above is attached the Vastus externus. The Adductor magnus is attached to the linea aspera, to its outer prolongation above and its inner prolongation below. Between the Vastus externus and the Adductor magnus are attached two muscles—viz., the Gluteus maximus above, and the short head of the Biceps below. Between the Adductor magnus and the Vastus internus four muscles are attached: the Iliacus and Pectineus above, the Adductor brevis and Adductor longus below. A little below the centre of the linea aspera is the **nutrient foramen** (*foramen nutricium*), the orifice of the **nutrient canal** (*canalis nutricius*), which is directed obliquely upward (proximally).

**Lateral Borders.**—The two lateral borders of the femur are only slightly marked, the outer one extending from the anterior inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner one from the spiral line at a point opposite the trochanter minor, to the anterior extremity of the internal condyle. The internal border marks the limit of attachment of the Crureus muscle internally.

**Anterior Surface.**—The anterior surface includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, slightly twisted, so that its upper part is directed forward and a little outward, its lower part forward and a little inward. To the upper three-fourths of this surface the Crureus is attached; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and affords attachment to the Subcrureus to a small extent.

**External Surface.**—The external surface includes the portion of bone between the external border and the outer lip of the linea aspera; it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle; to its upper three-fourths is attached the outer portion of the Crureus muscle.

**Internal Surface.**—The internal surface includes the portion of bone between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle: it is covered by the Vastus internus muscle.

**Lower Extremity.**—The lower extremity, larger than the upper, is of a cuboid form, flattened from before backward, and divided into two large eminences, the **condyles** (*condyli*, from κονδύλος, a knuckle), by an interval which presents a smooth depression in front called the **trochea** (*facies patellaris*), and a notch of considerable size behind—the **intercondylar notch** (*fossa intercondyloidea*). The **external condyle** (*condylius lateralis*) is the more prominent anteriorly, and is the broader both in the antero-posterior and transverse diameters. The **internal condyle** (*condylius medialis*) is the narrower, longer, and more prominent inferiorly. This difference in the length of the two condyles is only observed when the bone is perpendicular and depends upon the obliquity of the thigh bones, in consequence of their separation above at the articulation with the pelvis. If the femur is held obliquely, the surfaces of the two condyles will be seen to be nearly hori-
zontal. The two condyles are directly continuous in front, and form a smooth, trochlear surface, the *trochlea*, which articulates with the patella. It presents a median groove, which extends downward and backward to the intercondyloid notch; and two lateral convexities, of which the external is the broader, more prominent, and prolonged farther upward upon the front of the outer condyle. The external border of this articular surface is also more prominent, and ascends higher than the internal one. The intercondyloid notch lodges the crucial ligaments; it is bounded laterally by the opposed surfaces of the two condyles, and in front by the lower end of the shaft. Between the popliteal surface and the floor of the intercondyloid notch is an elevation (*linea intercondyloidea*), which affords attachment to the posterior ligament of the knee-joint.

**Outer or External Condyle (condylus lateralis).**—The outer surface of the external condyle presents, a little behind its centre, an eminence, the *outer tuberosity* (*epicondylus lateralis*); it is less prominent than the inner tuberosity, and gives attachment to the external lateral ligaments of the knee. Immediately beneath it is a groove, the *popliteal groove* (*sulcus popliteus*), which commences at a depression a little behind the centre of the lower border of this surface: the front part of this depression gives origin to the Popliteus muscle, the tendon of which is lodged in the groove during flexion of the knee. The groove is smooth, covered with cartilage in the recent state, and runs upward and backward to the posterior extremity of the condyle. The *inner surface* of the outer condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its posterior part, to the anterior crucial ligament. The *inferior surface* is convex, smooth, and broader than that of the internal condyle. The posterior extremity is convex and smooth: just above and to the outer side of the articular surface is a depression for the tendon of the outer head of the Gastrocnemius, above which is the origin of the Plantaris.

**Inner or Internal Condyle (condylus medialis).**—The *inner surface* of the inner condyle presents a convex eminence, the *inner tuberosity* (*epicondylus medialis*), rough for the attachment of the internal lateral ligament. The *outer side* of the inner condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its anterior part, to the posterior crucial ligament. Its *inferior or articular surface* is convex, and presents a less extensive surface than the external condyle. Just above the articular surface of the condyle, behind, is a depression for the tendon of origin of the inner head of the Gastrocnemius.

**Structure.**—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal well formed; but above and below this the cylinder gradually becomes thinner, owing to a separation of the layers of the bone into cancelli, which project into the medullary canal and finally obliterate it, so that the upper and lower ends of the shaft, and the articular extremities more especially, consist of cancellated tissue invested by a thin, compact layer.

The arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One, starting from the top of the
head, the upper surface of the neck, and the great trochanter, converge to the inner circumference of the shaft (Figs. 163 and 164); these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellæ intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions. In the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the femoral spur (calcar femorale), which com-

Fig. 164.—Right femur, upper extremity, ground frontal section, from in front. (Spalteholz.)
mences at the point where the neck joins the shaft midway between the lesser trochanter and the internal border of the shaft of the bone, and extends in the direction of the digital fossa (Fig. 165). This materially strengthens this portion of the bone. Another point in connection with the structure of the neck of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck; and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the true neck, and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge toward the outer surface of the bone. In the lower end the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, however, horizontal planes of cancellous tissue are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of rectangular areas.

Articulations. — With three bones: the os innominatum, tibia, and patella.

Development (Fig. 166). — The femur is developed by five centres: one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification: this commences in the shaft, at about the seventh week of foetal life, the centres of ossification in the epiphyses appearing in the following order: First, in the lower end of the bone, at the ninth month of foetal life (from this the condyles and tuberosities are

1 Bigelow on the Hip, p. 121.
2 This is said to be the only epiphysis in which ossification begins before birth; though according to some observers, the centre for the upper epiphysis of the tibia also appears before birth.
THE FEMUR, OR THIGH BONE

formed); in the head at the end of the first year after birth; in the great trochanter, during the fourth year; and in the lesser trochanter, between the thirteenth and fourteenth. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: their junction does not commence until after puberty, the lesser trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year.

Attachment of Muscles.—To twenty-three. To the great trochanter: the Gluteus medius, Gluteus minimus, Pyriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris. To the lesser trochanter: the Psoas magnus and the Iliacus below it. To the shaft: the Vastus externus, Gluteus maximus, short head of the Biceps, Vastus internus, Adductor magnus, Pectineus, Adductor brevis, Adductor longus, Crureus, and Subcureus. To the condyles: the Gastrocnemius, Plantaris, and Popliteus.

Surface Form.—The femur is covered with muscles, so that in fairly muscular subjects the shaft is not to be detected through its fleshy covering, and the only parts accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. The external surface of the great trochanter is to be felt, especially in certain positions of the limb. Its position is generally indicated by a depression, owing to the thickness of the Gluteus medius and minimus, which project above it. When, however, the thigh is flexed, and especially if crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a line with the spine of the os pubis, and its exact level is indicated by a line drawn from the anterior superior spinous process of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischium. This is known as Nelaton's line. The outer and inner condyles of the lower extremity are easily to be felt. The outer one is more subcutaneous than the inner one and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognized. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp tubercle for the insertion of the tendon of the Adductor magnus can be recognized without difficulty. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trochlear surface of the femur can be made out above the patella.

Surgical Anatomy.—There are one or two points about the ossification of the femur bearing on practice to which allusion must be made. It has been stated above that the lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of the ossific centre in newly born children found dead is, therefore, a proof that the child has arrived at the full period of utero-gestation, and is always relied upon in medico-legal investigations. The position of the epiphyseal line should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the kneé, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphyseal cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render it almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is of interest principally on account of its being the seat of origin of a large number of cases of tuberculous disease of the hip-joint. The disease commences in the majority of cases in the highly vascular and growing tissue in the neighborhood of the epiphysis, and from here extends into the joint. In the condition known as coxa vara the head of the femur falls to a lower level than normal. The angle between the neck and shaft is greatly diminished and may become a right angle or the head may actually descend to a lower level than that of the trochanter. The neck is also bent with a convexity forward; coxa vara is due to rickets.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the shaft; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or of the great trochanter. The first of these, fracture of the neck, is usually termed intra-articular fracture, but this is scarcely a correct designation, as owing to the attachment of the capsular ligament, the fracture may be partly within and partly without the capsule, when the fracture occurs at the lower part of the neck. It generally occurs in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of the fracture
taking place in old people is in consequence of the degenerative changes which the bone has undergone. Merkel believes that it is mainly due to the absorption of the calcar femorale. These fractures are occasionally impacted. As a rule they unite by fibrous tissue, and frequently no union takes place, and the surfaces of the fracture become smooth and eburnated. The lack of reparative power in intracapsular fracture is due to lack of apposition of the fragments and diminution in the amount of blood sent to the smaller fragment. The head of the bone receives blood from the neck through the reflected portions of the capsule and through the Ligamentum teres. A fracture cuts off the supply by the neck and by the reflected portions of the capsule.

Fractures at the junction of the neck with the great trochanter are usually termed extra-capsular, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a blow or fall laterally on the hip. From the manner in which the accident is caused, the neck of the bone is driven into the trochanter, where it may remain impacted or the trochanter may be split up into two or more fragments, and thus no fixation takes place.

Fractures of the great trochanter may be either "oblique fracture through the trochanter major, without impaling the neck of the bone" (Astley Cooper), or separation of the great trochanter. Most of the recorded cases of this latter injury occurred in young persons, and were probably cases of separation of the epiphysis of the great trochanter. Separation of the epiphysis of the head of the femur has been said to occur, but has probably never been verified by post-mortem examination.

Fractures of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence or by muscular action. Fractures of the upper third of the shaft are almost always the result of indirect violence, whilst those of the lower third are the result, for the most part, of direct violence. In the middle third fractures occur from both forms of injury in about equal proportions. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture, separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur and also the bones of the leg are frequently the seat of acute osteomyelitis in young children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Tumors not unfrequently are found growing from the femur: the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone; and exostosis, which is commonly found originating in the neighborhood of the epiphyseal cartilage of the lower end.

Genu varum is a form of bow-leg in which the tibia and femur are curved outward, the knees being widely separated. Both extremities are usually affected. In early life the disease is due to rickets. In elderly people it may be due to arthritis deformans. Genu valgum (knock-knee) is a condition in which the knees are close together, the feet are wide apart, and the internal lateral ligament of the knee-joint is stretched. It is due to excessive growth of the inner condyle of the femur, the shaft of the femur curving inward. It may be due to rickets, attitude of an occupation, or flat-foot, and one or both knees may be affected.

THE LEG.

The skeleton of the leg consists of three bones: the patella, a large sesamoid bone, placed in front of the knee; the tibia; and the fibula.

The Patella, or Knee-cap (Figs. 167, 168).

The patella (patella, a small pan), the knee-cap or knee-pan, is a flat, triangular bone, situated at the anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor. It resembles these bones (1) in its being developed in a tendon; (2) in its centre of ossification presenting a knotty or tuberculated outline; (3) in its structure being composed mainly of dense cancellous tissue, as in the other sesamoid bones. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an anterior and a posterior surface, three borders, and an apex.
Surfaces. Anterior Surface.—The anterior surface is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striae. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patellae. It is separated from the integument by a bursa.

Posterior Surface.—The posterior surface presents a smooth, oval-shaped, articular surface (facies articularis), covered with cartilage in the recent state, and divided into two facets by a vertical ridge, which descends from the superior border toward the inferior angle of the bone. The ridge corresponds to the groove on the trochlear surface of the femur, and the two facets to the articular surfaces of the two condyles; the outer facet, for articulation with the outer condyle, being the broader and deeper. This character serves to indicate the side to which the bone belongs. Below the articular surface is a rough, convex, non-articular depression, the lower half of which gives attachment to the ligamentum patellae, the upper half being separated from the head of the tibia by adipose tissue.

Borders. Superior Border.—The superior border (basis patellae) is thick, and sloped from behind, downward and forward: it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus and Crureus muscles.

Lateral Borders.—The lateral borders are thinner, converging below. They give attachment to that portion of the Quadriceps extensor derived from the external and internal Vasti muscles.

The Apex (apex patellae).—The apex is pointed, and gives attachment to the ligamentum patellae.

Structure.—It consists of a nearly uniform, dense cancellous tissue covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface toward the other parts of the bone.

Development.—By a single centre, which makes its appearance, according to Béclard, about the third year. In two instances Mr. Pick has seen this bone cartilaginous throughout, at a much later period (six years). More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulations.—With the two condyles of the femur.

Attachment of Muscles.—To four: the Rectus, Crureus, Vastus internus, and Vastus externus. These muscles, joined at their insertion, constitute the Quadriceps extensor cruris.

Surface Form.—The external surface of the patella can be seen and felt in front of the knee. In the extended position of the limb the internal border is a little more prominent than the outer, and if the Quadriceps extensor is relaxed the bone can be moved from side to side and appears to be loosely fixed. If the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly fixed against the femur.

Surgical Anatomy.—The main surgical interest about the patella is in connection with fractures, which are of common occurrence. They may be produced by muscular action; that is to say, by violent contraction of the Quadriceps extensor while the limb is in a position of semi-flexion, so that the bone is snapped across the condyles; or by direct violence, such as

falls on the knee. Most fractures are due to muscular action; in fact, the patella is more often broken by muscular action than is any other bone. In fractures by muscular action the line of fracture is transverse. In fractures by direct force the line of fracture may be oblique, longitudinal, stellate, or the bone variously comminuted. The principal interest in these cases attaches to their treatment. Owing to the wide separation of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Various plans, including opening the joint and suturing the fragments, have been advocated for overcoming this difficulty. In many cases a portion of fascia or capsule gets between the fragments. In such a condition operation is necessary.

In the larger number of cases of fracture of the patella the knee-joint is involved, the cartilage which covers its posterior surface being torn, the synovial membrane lacerated, the lateral fibrous expansions ruptured, and the patellar bursa torn open. In cases of fracture from direct violence, however, this need not necessarily happen, the lesion may involve only the superficial part of the bone; and, as Morris has pointed out, it is an anatomical possibility, in complete fracture, if the lesion involve only the lower and non-articular part of the bone, for it to take place without injury to the synovial membrane.

The Tibia, or Shin Bone (Figs. 169, 170).

The tibia (tibia, a flute or pipe) is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone in the skeleton. It is prismatic in form, expanded above, where it enters into the knee-joint, more slightly enlarged below. In the male its direction is vertical and parallel with the bone of the opposite side; in the female it has a slightly oblique direction downward and outward, to compensate for the oblique direction of the femur inward. It presents for examination a shaft and two extremities.

Upper Extremity.—The upper extremity, or head, is large, and expanded on each side into two lateral eminences, the internal and external tuberosities (condylus medialis and condylus lateralis). Superiorly, each tuberosity presents a smooth, concave surface (facies articularis superior), which articulates with a condyle of the femur. The internal, articular surface is longer, deeper, and narrower than the external, oval from before backward, to articulate with the internal condyle; the external one is broader and more circular, concave from side to side, but slightly convex from before backward, especially at its posterior part, where it is prolonged on to the posterior surface for a short distance, to articulate with the external condyle. Between the two articular surfaces, and nearer the posterior than the anterior aspect of the bone, is an eminence, the spinous process of the tibia (eminentia intercondyloidea); surmounted by a prominent tubercle on each side (the tuberculum intercondyloideum mediale and the tuberculum intercondyloideum laterale), on to the lateral aspect of which the facets just described are prolonged; in front and behind the spinous process is a rough depression
The anterior surfaces of the tuberosities are continuous with one another, forming a single large surface, which is somewhat flattened: it is triangular, broad above, and perforated by large vascular foramina; narrow below, where it terminates in a prominent oblong elevation of large size, the tubercle of the tibia (tuberositas tibia); the lower half of this tubercle is rough, for the attachment of the ligamentum patellae; the upper half presents a smooth facet supporting, in the recent state, a bursa which separates the ligament from the bone. Posteriorly the tuberosities are separated from each other by a shallow depression, the popliteal notch (incisura poplitea), which gives attachment to part of the posterior crucial ligament and part of the posterior ligament of the knee-joint. The inner tuberosity presents posteriorly a deep transverse groove, for the insertion of one of the fasciculi of the tendon of the Semi-membranosus. Its lateral surface is convex, rough, and prominent, and gives attachment to the internal lateral ligament. The outer tuberosity presents posteriorly a flat articular facet (facies articularis fibularis), nearly circular in form, directed downward, backward, and outward, for articulation with the fibula. Its lateral surface is convex and rough, more prominent in front than in the internal, and presents a prominent rough eminence, situated on a level with the upper border of the tubercle of the tibia at the junction of its anterior and outer surfaces, for the attachment of the ilio-tibial band. Just below this the Extensor longus digitorum and a slip from the Biceps are attached. The infraglenoid margin (margo infraglenoidalis) is at the outer edge of the superior articular surface. From this point the bone rapidly narrows distally.

Shaft of the Tibia (corpus tibiae).—The shaft of the tibia is of a triangular prismatic form, broad above, gradually decreasing in size to its most slender part, at the commencement of its lower fourth, where fracture most frequently occurs; it then enlarges again toward its lower extremity. It presents for examination three borders and three surfaces.

Anterior Border.—The anterior border, the most prominent of the three, is called the crest of the tibia (crista anterior), or, in popular language, the shin; it commences above at the tubercle, and terminates below at the anterior margin of the inner malleolus. This border is very prominent in the upper two-thirds of its extent, smooth and rounded below. It presents a very flexuous course, being usually curved outward above and inward below; it gives attachment to the deep fascia of the leg.

Internal Border (margo medialis).—The internal border is smooth and rounded above and below, but more prominent in the centre; it commences at the back part of the inner tuberosity, and terminates at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and to some fibres of the Popliteus muscle, and its middle third to some fibres of the Soleus and Flexor longus digitorum muscles.

External Border (crista interossea).—The external border, or interosseous ridge, is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

Internal Surface (facies medialis).—The internal surface is smooth, convex, and broader above than below; its upper third, directed forward and inward, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forward as the anterior border; in the rest of its extent it is subcutaneous.
External Surface (facies lateralis).—The external surface is narrower than the internal; its upper two-thirds presents a shallow groove for the attachment of the Tibialis anticus muscle; its lower third is smooth, convex, curves gradually forward to the anterior aspect of the bone, and is covered from within outward by the tendons of the following muscles: Tibialis anticus, Extensor proprius hallucis, Extensor longus digitorum.

Posterior Surface (facies posterior).—The posterior surface (Fig. 170) presents, at its upper part, a prominent ridge, the popliteal line or the oblique line of the tibia ( linea poplitea), which extends from the back part of the articular facet for the fibula obliquely downward, to the internal border, at the junction of its upper and middle thirds. It marks the lower limit for the insertion of the Popliteus muscle, and serves for the attachment of the popliteal fascia and part of the Soleus, Flexor longus digitorum, and Tibialis posticus muscles; the triangular concave surface, above and to the inner side of this line, gives attachment to the Popliteus muscle. The middle third of the posterior surface is divided by a vertical ridge into two lateral halves: the ridge is well marked at its commencement at the oblique line, but becomes gradually indistinct below; the inner and broader half gives attachment to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the bone presents a smooth surface covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles. Immediately below the oblique line is the nutritive foramen ( foramen nutricium), which is large and directed obliquely downward. It is the opening of the nutrient canal, which is directed toward the periphery.

Lower Extremity.—The lower extremity, much smaller than the upper, presents five surfaces; it is prolonged downward, on its inner side, to a strong process, the internal malleolus ( malleolus medialis).

Inferior Surface (facies articularis inferior).—The inferior surface of the bone is quadrilateral, and smooth for articulation with the astragalus. This surface is concave from before backward, and broader in front than behind. It is traversed from before backward by a slight elevation, separating two lateral depressions. It is narrow internally, where the articular surface becomes continuous with that on the inner malleolus ( facies articularis malleolaris).

Anterior Surface.—The anterior surface of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes; its lower margin presents a rough transverse depression, for the attachment of the anterior ligament of the ankle-joint.

Posterior Surface.—The posterior surface presents a superficial groove directed obliquely downward and inward, continuous with a similar groove on the posterior surface of the astragalus, and serving for the passage of the tendon of the Flexor longus hallucis.

External Surface.—The external surface presents a triangular rough depression for the attachment of the internal interosseous ligament, connecting it with the fibula; the lower part of this depression, the fibular notch (incisura fibularis), is smooth, covered with cartilage in the recent state, and articulates with the fibula. This surface is bounded by two prominent borders, continuous above with the interosseous ridge; they afford attachment to the anterior inferior and posterior inferior fibio-fibular ligaments.

Internal Surface.—The internal surface of the lower extremity is prolonged downward to form a strong pyramidal process, flattened from without inward—the internal malleolus ( malleolus medialis). The inner surface of this process is convex and subcutaneous; its outer surface is smooth and slightly concave, and articulates with the astragalus; its anterior border is rough, for the attachment of the anterior fibres of the internal lateral or Deltoid ligament; its posterior border
presents a broad and deep groove (*sulcus malleolaris*), directed obliquely downward and inward, which is occasionally double; this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum muscles. The summit of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligament of the ankle-joint.

**Structure.**—Like that of the other long bones. At the junction of the middle and lower third, where the bone is smallest, the wall of the shaft is thicker than in other parts, in order to compensate for the smallness of the calibre of the bone.

**Development.**—By three centres (Fig. 172): one for the shaft and one for each extremity. Ossification commences in the centre of the shaft about the seventh week, and gradually extends toward either extremity. The centre for the upper epiphysis appears before or shortly after birth; it is flattened in form, and has a thin, tongue-shaped process in front which forms the tubercle. That for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one about the twentieth year. Two additional centres occasionally exist—one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

**Articulations.**—With three bones: the femur, fibula, and astragalus.

**Attachment of Muscles.**—To twelve: to the inner tuberosity, the Semimembranosus; to the outer tuberosity, the Tibialis anticus and Extensor longus digitorum and Biceps; to the shaft, its internal surface, the Sartorius, Gracilis, and Semitendinosus; to its external surface, the Tibialis anticus; to its posterior surface, the Popliteus, Soleus, Flexor longus digitorum, and Tibialis posticus; to the tubercle, the ligamentum patellae, by which the Quadriceps extensor muscle is inserted into the tibia. In addition to these muscles, the Tensor fasciae femoris is inserted indirectly into the tibia, through the ilio-tibial band, and the Peroneus longus occasionally derives a few fibres of origin from the outer tuberosity.

**Surface Form.**—A considerable portion of the tibia is subcutaneous and easily to be felt. At the upper extremity the tuberosities are to be recognized just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, may be felt a prominent tubercle for the insertion of the ilio-tibial band. In front of the upper end of the bone, between the tuberosities, is the tubercle of the tibia, forming an oval eminence which is continuous below with the anterior border or crest of the bone. This border can be felt, forming the prominence of the shin, in the upper two-thirds of its extent as a sharp and flexuous ridge, curved outward above and inward below. In the lower third of the leg the border disappears, and the bone is concealed by the tendons of the muscles on the front of the leg. Internal to the anterior border is to be felt the broad internal surface of the tibia, slightly encroached upon by the muscles in front and behind. It commences above at the wide expanded inner tuberosity, and terminates below at the internal malleolus. The internal malleolus is a broad prominence situated on a higher level and somewhat farther forward than the external malleolus. It overhangs the inner border of the arch of the foot. Its anterior border is nearly straight; its posterior border presents a sharp edge which forms the inner margin of the groove for the tendon of the Tibialis posticus muscle.
The Fibula, or Calf Bone (Figs. 169, 170).

The fibula (\textit{fibula}, a clasp) is situated at the outer side of the leg. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones; it is placed on the outer side of the tibia, with which it is connected above and below. Its upper extremity is small, placed toward the back of the head of the tibia and below the level of the knee-joint, and excluded from its formation; the lower extremity inclines a little forward, so as to be on a plane anterior to that of the upper end, projects below the tibia, and forms the outer ankle. It presents for examination a \textit{shaft} and two \textit{extremities}.

**Upper Extremity.**—The upper extremity, or \textit{head} (\textit{capitulum fibulae}), is of an irregular quadrate form, presenting above a flattened articular facet, directed upward, forward, and inward, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the \textit{styloid process of the fibula} (\textit{apex capituli fibulae}), which projects upward from the posterior part of the head. The \textit{prominence} gives attachment to the tendon of the Biceps muscle and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The \textit{summit} of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior part of the Peroneus longus, and the adjacent surface gives attachment to the anterior superior tibio-fibular ligament; and behind, another tubercle for the attachment of the posterior superior tibio-fibular ligament and the upper fibres of the Soleus muscle.

**Shaft of the Fibula** (\textit{corpus fibulae}).—The shaft presents four borders—the antero-external, the antero-internal, the postero-external, and the postero-inner; and four surfaces—anterior, posterior, internal, and external.

**Antero-external Border** (\textit{crista anterior}).—The antero-external border commences above in front of the head, runs vertically downward to a little below the middle of the bone, and then, curving somewhat outward, bifurcates so as to embrace the triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the extensor muscles on the anterior surface of the leg from the Peroneus longus and brevis muscles on the outer surface.

**Antero-internal Border** (\textit{crista interossea}).—The antero-internal border, or \textit{interosseous ridge}, is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It commences above, just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and terminates below at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, which separates the extensor muscles in front from the flexor muscles behind.

**Postero-external Border** (\textit{crista lateralis}).—The postero-external border is prominent; it commences above at the base of the styloid process, and terminates below in the posterior border of the outer malleolus. It is directed outward above, backward in the middle of its course, backward and a little inward below, and gives attachment to an aponeurosis which separates the Peronei muscles on the outer surface of the shaft from the flexor muscles on its posterior surface.

**Postero-internal Border** (\textit{crista medialis}).—The postero-internal border, sometimes called the \textit{oblique line}, commences above at the inner side of the head, and terminates by becoming continuous with the antero-internal border or inter-
osseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus above and the Flexor longus hallucis below.

**Anterior Surface** (*facies anterior*).—The anterior surface is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the attachment of three muscles, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis.

**External Surface** (*facies lateralis*).—The external surface is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved, is directed outward in the upper two-thirds of its course, backward in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peroneus longus and brevis muscles.

**Internal Surface** (*facies medialis*).—The internal surface is the interval included between the antero-internal and the postero-internal borders. It is directed inward, and is grooved for the attachment of the Tibialis posticus muscle.

**Posterior Surface** (*facies posterior*).—The posterior surface is the space included between the postero-external and the postero-internal borders, it is continuous below with the rough triangular surface above the articular facet of the outer malleolus; it is directed backward above, backward and inward at its middle, directly inward below. Its upper third is rough, for the attachment of the Soleus muscle; its lower part presents a triangular rough surface, connected to the tibia by a strong interosseous ligament, and between these two points the entire surface is covered by the fibres of origin of the Flexor longus hallucis muscle. At about the middle of this surface is the *nutrient foramen* (*foramen nutrientium*). It opens into the *nutrient canal* (*canalis nutrientius*), which is directed downward.

**Lower Extremity.**—The lower extremity, or *external malleolus* (*malleolus lateralis*), is of a pyramidal form, somewhat flattened from without inward, and is longer, and descends lower than the internal malleolus. Its *external surface* is convex, subcutaneous, and continuous with the triangular (also subcutaneous) surface on the outer side of the shaft. The *internal surface* presents in front a smooth triangular facet (*facies articularis malleoli*), broader above than below, and convex from above downward, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the articular surface is a rough depression which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The *anterior border* is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The *posterior border* is broad and marked by a shallow groove (*sulcus malleolaris*), for the passage of the tendons of the Peroneus longus and brevis muscles. The *summit* is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

In order to distinguish the side to which the bone belongs, hold it with the lower extremity downward and the broad groove for the Peronei tendons backward—*i.e.*, toward the holder; the triangular subcutaneous surface will then be directed to the side to which the bone belongs.

**Articulations.**—With two bones: the tibia and astragalus.

**Development.**—By three centres (Fig. 173); one for the shaft, and one for each extremity. Ossification commences in the shaft about the eighth week of fetal life, a little later than in the tibia, and extends gradually toward the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one about the fourth year. The lower epiphysis, the first in which ossification commences, becomes united to the shaft
about the twentieth year; the upper epiphysis joins about the twenty-fifth year. Ossification appearing first in the lower epiphysis is contrary to the rule which prevails with regard to the commencement of ossification in epiphyses—viz., that epiphysis toward which the nutrient artery is directed commences to ossify last; but it follows the rule which prevails with regard to the union of epiphyses, by uniting first.

**Attachment of Muscles.**—To nine: to the head, the Biceps, Soleus, and Peroneus longus; to the shaft, its anterior surface, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis; to the internal surface, the Tibialis posticus; to the posterior surface, the Soleus and Flexor longus hallucis; to the external surface, the Peroneus longus and brevis.

**Surface Form.**—The only parts of the fibula which are to be felt are the head and the lower part of the external surface of the shaft and the external malleolus. The head is to be seen and felt behind and to the outer side of the outer tuberosity of the tibia. It presents a small, prominent triangular eminence slightly above the level of the tubercle of the tibia. The external malleolus presents a narrow elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the Peroneus tertius in front and the other two Peronei tendons behind.

**Surgical Anatomy.**—In fractures of the bones of the leg both bones are usually fractured, but either bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused either by direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is usually at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at rather a higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are usually the result of indirect violence, and the direction of the fracture is from behind, downward, forward, and inward in many cases, but may be downward and outward or downward and backward. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture usually commences as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body whilst the foot is fixed.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia and fibula, like the femur, are frequently the seat of acute osteomyelitis. Tuberculous abscess is more frequently met with in the cancellous tissue of the head and lower end of the tibia than in any other bone of the body. The abscess is of small size, very chronic, and probably the result of tuberculous osteitis in the highly vascular growing tissue at the end of the shaft near the epiphysial cartilage in the young subject. Such an abscess in bone is called Brodie's abscess.

The tibia is the bone which is most frequently and most extensively distorted in rickets. It gives way at the junction of the middle and lower third, its weakest part, and presents a curve forward and outward. Bow-leg is due to outward curvature of the femur, tibia, and fibula, the bend being about the junction of the shafts and lower extremities.

**THE FOOT (Figs. 174, 175).**

The skeleton of the foot consists of three divisions: the tarsus, metatarsus, and phalanges.

Fig. 175.—Bones of the right foot. Plantar surface.
The Tarsus (Ossa Tarsi).

The bones of the tarsus are seven in number—viz., the calcaneus or os calcis, astragalus, cuboid, scaphoid, internal, middle, and external cuneiform.

The Calcaneus, or Heel Bone (Fig. 176).—It is also called the os calcis. The name is derived from calx, the heel. The heel bone is the largest and strongest of the tarsal bones. It is irregularly cuboidal in form, having its long axis directed forward and outward. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It is composed of a body (corpus calcanei), an anterior extremity or greater process, and a posterior extremity or tuberosity (tuber calcanei). It presents for examination six surfaces: superior, inferior, external, internal, anterior, and posterior.

Superior Surface.—The superior surface is formed behind by the upper aspect of that part of the os calcis which projects backward to form the heel. It varies in length in different individuals; is convex from side to side, concave from before backward, and corresponds above to a mass of adipose substance placed in front of the tendo Achillis. In the middle of the superior surface are two (sometimes three) articular facets, separated by a broad shallow groove (sulcus calcanei), which is directed obliquely forward and outward, and is rough for the attachment of the interosseous ligament connecting the astragalus and os calcis. When the calcaneus is in contact with the astragalus this groove is converted into a canal (sinus tarsi). Of the articular surfaces, the external or posterior articular surface (facies articularis calcanea posterior) is the larger, and is situated on the body
of the bone: it is of an oblong form, wider behind than in front, and convex from before backward. The internal or anterior articular surface is usually divided into two facets. The anterior facet is the facies articularis calcanea anterior, and it supports the head of the astragalus. The more posteriorly situated facet is the facies articularis calcanea media. It articulates with the middle facet on the under surface of the astragalus. The internal articular surface is supported on a projecting process of bone, called the lesser process of the calcaneus (sustentaculum tali); it is also oblong, concave longitudinally, and sometimes subdivided into two parts, which differ in size and shape. More anteriorly is seen the upper surface of the greater process of the calcaneus, marked by a rough depression for the attachment of numerous ligaments, and a tubercle for the origin of the Extensor brevis digitorum muscle.

Inferior Surface.—The inferior surface is narrow, rough, uneven, wider behind than in front and convex from side to side; it is bounded posteriorly by two tubercles separated by a rough depression; the external tubercle (processus lateralis tuberis calcanei), small, prominent, and rounded, gives attachment to part of the Abductor minimi digiti: the internal tubercle (processus medialis tuberis calcanei), broader and larger, for the support of the heel, gives attachment, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum muscles and plantar fascia; the depression between the tubercles gives attachment to the Abductor minimi digiti. The rough surface in front of the tubercles gives attachment to the long plantar ligament and to the outer head of the Flexor accessorius muscle; while to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of it, is attached the short plantar ligament.

External Surface.—The external surface is broad, flat, and almost subcutaneous; it presents near its centre a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part this surface gives attachment to the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves, separated by an elevated ridge which varies much in size in different bones; it is named the peroneal spine or tubercle (processus trochlearis), and gives attachment to a fibrous process from the external annular ligament. The superior groove transmits the tendon of the Peroneus brevis; the inferior groove the tendon of the Peroneus longus.

Internal Surface.—The internal surface is deeply concave; it is directed obliquely downward and forward, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords attachment to part of the Flexor accessorius muscle. At its upper and fore part it presents an eminence of bone, the lesser process of the calcaneum (sustentaculum tali), which projects horizontally inward, and to it a slip of the tendon of the Tibialis posticus is attached. This process is concave above, and supports the anterior articular surface of the astragalus; below, it is grooved for the tendon of the Flexor longus hallucis. Its free margin is rough, for the attachment of part of the internal lateral ligament of the ankle-joint.

Anterior Surface (facies articularis cuboidea).—The anterior surface, of a somewhat triangular form, articulates with the cuboid. It is concave from above downward and outward, and convex in the opposite direction. Its inner border gives attachment to the inferior calcaneo-scaphoid ligament.

Posterior Surface.—The posterior surface is rough, prominent, convex, and wider below than above. The posterior extremity is the projection of the heel. It is called the tuberosity (tuber calcanei). Its lower part is rough, for the attachment of the tendo Achilles and the tendon of the Plantaris muscle; its upper part is smooth, and is covered by a bursa which separates the tendons from the bone.
Articulations.—With two bones; the astragalus and cuboid.

Attachment of Muscles.—To eight: part of the Tibialis posticus, the tendo Achillis, Plantaris, Abductor hallucis, Abductor minimi digitii, Flexor brevis digitorum, Flexor accessorius, and Extensor brevis digitorum.

The Astragalus, or Ankle Bone (talus) (Fig. 177).—The astragalus (αστραγαλός, a die) is the largest of the tarsal bones, next to the os calcis. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon the os calcis, and joined in front to the scaphoid. This bone may easily be recognized by its large rounded head, by the broad articular facet on its upper convex surface, and by the two articular facets separated by a deep groove on its under concave surface. It

![Figure 177](Image)

is divided into a body (corpus tali), which supports the trochlear surface; the head (caput tali), which is in front of the body; and the neck (collum tali), the constricted part between the head and body. The astragalus presents six surfaces for examination.

Superior Surface.—The superior surface presents, behind, a broad smooth trochlear surface (trochlea tali) for articulation with the tibia. The trochlea is broader in front than behind, convex from before backward, slightly concave from side to side; in front of it is the upper surface of the neck of the astragalus, rough for the attachment of ligaments.

 Inferior Surface.—The inferior surface presents two articular facets separated by a deep groove (sulcus tali). The groove runs obliquely forward and outward, becoming gradually broader and deeper in front: it corresponds with a similar groove upon the upper surface of the calcaneus, and forms, when articulated with that bone, a canal (sinus tarsi), filled up in the recent state by the interosseous calcaneo-astragaloid ligament. Of the two articular facets, the posterior articular facet (facies articularis calcanea posterior) is the larger, of an oblong form and deeply concave from side to side; the anterior articular facet is shorter and narrower, of an elongated oval form, convex longitudinally, and often subdivided into two by an elevated ridge; of these, the posterior (facies articularis calcanea media) articulates with the lesser process of the os calcis; the anterior (facies articularis calcanea anterior), with the upper surface of the inferior calcaneo-scaphoid ligament.

Internal Surface.—The internal surface presents at its upper part a pear-shaped articular facet (facies malleolaris medialis) for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression, for the attachment of the deep portion of the internal lateral ligament.

External Surface.—The external surface presents a large triangular facet (facies malleolaris lateralis), covered with cartilage and concave from above downward
for articulation with the external malleolus; it is called the external process (processus lateralis tali), and passes outward and downward from the triangular facet. The triangular facet is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint.

Anterior Surface (facies articularis navicularis).—The anterior surface of the head of the astragalus is convex and rounded, smooth, of an oval form, and directed obliquely inward and downward; it articulates with the scaphoid. On its under and inner surface is a small facet, continuous in front with the articular surface of the head, and behind with the smaller facet for the os calcis. This rests on the inferior calcaneo-scaphoid ligament, being separated from it by the synovial membrane, which is prolonged from the anterior calcaneo-astragaloid joint to the astragalo-scaphoid joint. The head is surrounded by a constricted portion, the neck of the astragalus (collum tali).

Posterior Surface.—The posterior surface is narrow, and traversed by a groove (sulcus m. flexoris hallucis longi), which runs obliquely downward and inward, and transmits the tendon of the Flexor longus hallucis, external to which is the prominent external tubercle (processus posterior tali), to which the posterior fasciculus of the external lateral ligament is attached. This tubercle is sometimes separated from the rest of the astragalus, and is then known as the os trigonum. To the inner side of the groove is the less marked internal tubercle.

To ascertain to which foot the bone belongs, hold it with the broad articular surface upward, and the rounded head forward; the lateral triangular articular surface for the external malleolus will then point to the side to which the bone belongs.

Articulations.—With four bones: tibia, fibula, os calcis, and scaphoid.

The Cuboid (os cuboides) (Fig. 178).—The cuboid, from κυβος, a cube; κοιδος, like, is placed on the outer side of the foot, in front of the os calcis, and

behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed inward, its apex outward. It may be distinguished from the other tarsal bones by the existence of a deep groove on its under surface, for the tendon of the Peroneus longus muscle. It presents for examination six surfaces: three articular and three non-articular.

Non-articular Surfaces.—The non-articular surfaces are the superior, inferior, and external. The superior or dorsal surface, directed upward and outward, is rough, for the attachment of numerous ligaments. The inferior or plantar surface presents in front a deep groove, the peroneal groove (sulcus m. peronaei longi), which runs obliquely from without, forward and inward; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which is attached the long calcaneo-cuboid ligament. The ridge terminates externally in an eminence, the tuberosity of the cuboid (tuberositas ossis cuboidei), the surface of which presents a convex facet, for articulation with the sesamoid bone
of the tendon contained in the groove. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of the Flexor brevis hallucis, and a fasciculus from the tendon of the Tibialis posticus. The external surface, the smallest and narrowest of the three, presents a deep notch formed by the commencement of the peroneal groove.

Articular Surfaces.—The articular surfaces are the posterior, anterior, and internal. The posterior surface is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The anterior surface, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets; the inner one, quadrilateral in form, articulates with the fourth metatarsal bone; the outer one, larger and more triangular, articulates with the fifth metatarsal. The internal surface is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform bone; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

To ascertain to which foot the bone belongs, hold it so that its under surface, marked by the peroneal groove, looks downward, and the large concavo-convex articular surface backward toward the holder: the narrow non-articular surface, marked by the commencement of the peroneal groove, will point to the side to which the bone belongs.

Articulations.—With four bones: the os calcis, external cuneiform, and the fourth and fifth metatarsal bones; occasionally with the scaphoid.

Attachment of Muscles.—Part of the Flexor brevis hallucis and a slip from the tendon of the Tibialis posticus.

Scaphoid or Navicular Bone (os naviculare pedis) (Fig. 179).—The scaphoid is situated at the inner side of the tarsus, between the astragalus behind and the three cuneiform bones in front. It may be distinguished by its form, being concave behind, convex and subdivided into three facets in front.

Surfaces.—The anterior surface, of an oblong form, is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The posterior surface is oval, concave, broader externally than internally, and articulates with the rounded head of the astragalus. The superior surface is convex from side to side, and rough for the attachment of ligaments. The inferior is irregular, and also rough for the attachment of ligaments. The internal surface presents a rounded tubercular eminence, the tuberosity (tuberositas ossis navicularis), the lower part of which projects, and gives attachment to part of the tendon of the Tibialis posticus. The external surface is rough and irregular, for the attachment of ligamentous fibres, and occasionally presents a small facet for articulation with the cuboid bone.
To ascertain to which foot the bone belongs, hold it with the concave articular surface backward, and the convex dorsal surface upward; the external surface—i.e., the surface opposite the tubercle—will point to the side to which the bone belongs.

Articulations.—With four bones: astragalus and three cuneiforms; occasionally also with the cuboid.

Attachment of Muscles.—Part of the Tibialis posticus.

Cuneiform or Wedge Bones.—The cuneiform bones have received their name from their wedge-like shape (cuneus, a wedge; forma, likeness). They form, with the cuboid, the anterior row of the tarsus, being placed between the scaphoid behind, the three innermost metatarsal bones in front, and the cuboid externally. They are called the first, second, and third, counting from the inner to the outer side of the foot, and, from their position, internal, middle, and external.

Internal or First Cuneiform (os cuneiforme primum) (Fig. 180).—The internal cuneiform is the largest of the three. It is situated at the inner side of the foot, between the scaphoid behind and the base of the first metatarsal in front. It may be distinguished from the other two by its large size, and by its not presenting such a distinct wedge-like form. Without the others it may be known by the large, kidney-shaped anterior articulating surface and by the prominence on the inferior or plantar surface for the attachment of the Tibialis posticus. It presents for examination six surfaces.

Surfaces.—The internal surface is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval facet, into which the tendon of the Tibialis anticus is partially inserted; in the rest of its extent it is rough, for the attachment of ligaments. The external surface is concave, presenting, along its superior and posterior borders, a narrow, reversed, L-shaped surface, for articulation with the middle cuneiform behind and second metatarsal bone in front; in the rest of its extent it is rough, for the attachment of ligaments and part of the tendon of the Peroneus longus. The anterior surface, kidney-shaped, much larger than the posterior, articulates with the metatarsal bone of the great toe. The posterior surface is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the scaphoid. The inferior or plantar surface is rough, and presents a prominent tuberosity at its back part for the attachment of part of the tendon of the Tibialis posticus. It also gives attachment in front to part of the tendon of the Tibialis anticus. The superior surface is the narrowed pointed end of the wedge, which is directed upward and outward; it is rough for the attachment of ligaments.

To ascertain to which side the bone belongs, hold it so that its superior narrow edge looks upward, and the long, kidney-shaped, articular surface forward; the external surface, marked by its vertical and horizontal articular facets, will point to the side to which it belongs.

Articulations.—With four bones: scaphoid, middle cuneiform, first and second metatarsal bones.

Attachment of Muscles.—To three: the Tibialis anticus and posticus, and Peroneus longus.
Middle or Second Cuneiform (os cuneiforme secundum) (Fig. 181).—The middle cuneiform, the smallest of the three, is of very regular wedge-like form, the broad extremity being placed upward, the narrow end downward. It is situated between the other two bones of the same name, and articulates with the scaphoid behind and the second metatarsal in front. It is smaller than the external cuneiform bone, from which it may be further distinguished by the L-shaped articular facet, which runs round the upper and back part of its inner surface.

Surfaces.—The anterior surface, triangular in form and narrower than the posterior, articulates with the base of the second metatarsal bone. The posterior surface, also triangular, articulates with the scaphoid. The internal surface presents a reversed L-shaped articular facet, running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent, for the attachment of ligaments. The external surface presents posteriorly a smooth facet for articulation with the external cuneiform bone. The superior surface forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The inferior surface, pointed and tubercular, is also rough for ligamentous attachment and for the insertion of a slip from the tendon of the Tibialis posticus.

![Fig. 181. The left middle cuneiform. A. Antero-internal view. B. Postero-external view.](image1)

To ascertain to which foot the bone belongs, hold its superior or dorsal surface upward, the broadest edge being toward the holder: the smooth facet (limited to the posterior border) will then point to the side to which it belongs.

Articulations.—With four bones: scaphoid, internal and external cuneiform, and second metatarsal bone.

Attachment of Muscles.—A slip from the tendon of the Tibialis posticus is attached to this bone.

External or Third Cuneiform (os cuneiforme tertium) (Fig. 182).—The external cuneiform, intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upward, the narrow end downward. It occupies the centre of the front row of the tarsus, between the middle cuneiform internally, the cuboid externally, the scaphoid behind, and the third metatarsal in front. It is distinguished from the internal cuneiform bone by its more regular wedge-like shape and by the absence of the kidney-shaped articular surface: from the middle cuneiform, by the absence of the reversed L-shaped facet, and by the two articular facets which are present on both its inner and outer surfaces. It has six surfaces for examination.

Surfaces.—The anterior surface, triangular in form, articulates with the third metatarsal bone. The posterior surface articulates with the most external facet of the scaphoid, and is rough below for the attachment of ligamentous fibres. The internal surface presents two articular facets, separated by a rough depression; the anterior one, sometimes divided into two, articulates with the outer side of the base of the second metatarsal bone; the posterior one skirts the posterior border and articulates with the middle cuneiform; the rough depression between
the two gives attachment to an interosseous ligament. The external surface also presents two articular facets, separated by a rough non-articular surface; the anterior facet, situated at the superior angle of the bone, is small, and articulates with the inner side of the base of the fourth metatarsal; the posterior and larger one articulates with the cuboid; the rough, non-articular surface serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another, and covered by a prolongation of the same cartilage; the facets for articulation with the middle cuneiform and scaphoid are also continuous, but that for articulation with the cuboid is usually separate. The superior or dorsal surface is of an oblong square form, its posterior external angle being prolonged backward. The inferior or plantar surface is an obtuse rounded margin, and serves for the attachment of part of the tendon of the Tibialis posticus, part of the Flexor brevis hallucis, and ligaments.

To ascertain to which side the bone belongs, hold it with the broad dorsal surface upward, the prolonged edge backward; the separate articular facet for the cuboid will point to the proper side.

Articulations.—With six bones: the scaphoid, middle cuneiform, cuboid, and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To two: part of the Tibialis posticus, and Flexor brevis hallucis.

The number of tarsal bones may be reduced owing to congenital ankylosis which may occur between the os calcis and cuboid, the os calcis and scaphoid, the os calcis and astragalus, or the astragalus and scaphoid.

**The Metatarsal Bones (Ossa Metatarsalia).**

The metatarsal bones are five in number, and are numbered one to five, in accordance with their position from within outward; they are long bones, and present for examination a shaft and two extremities.

Common Characters.—The shaft (corpus) is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is slightly curved longitudinally, so as to be concave below, slightly convex above. On the plantar surface of the shaft of each bone is a nutrient foramen corresponding to the nutrient foramen in each metacarpal bone. The posterior or proximal extremity, or base (basis), is wedge-shaped, articularizing by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones, its dorsal and plantar surfaces being rough for the attachment of ligaments. The anterior or distal extremity, or head (capitulum), presents a terminal rounded articular surface, oblong from above downward, and extending farther backward below than above. Its sides are flattened and present a depression, surmounted by a tubercle, for ligamentous attachment. Its under surface is grooved in the middle line for the passage of the Flexor tendon, and marked on each side by an articular prominence continuous with the terminal articular surface.

Peculiar Characters. **First Metatarsal Bone or the Metatarsal Bone of the Great Toe (os metatarsale I).**—The first (Fig. 183) is remarkable for its great thickness, but is the shortest of all the metatarsal bones. The shaft is strong and of well-marked prismoid form. The posterior extremity presents, as a rule, no lateral articular facet, but occasionally on the outer side there is an oval facet by which it articulates with the second metatarsal bones. Its terminal articular surface is of large size and kidney-shaped; its circumference is grooved, for the tarso-metatarsal ligaments, and internally gives attachment to part of the tendon of the Tibialis anticus muscle; its inferior angle presents a rough oval prominence, the tuberosity (tuberositas ossis metatarsalis I), for the insertion of the tendon of the Peroneus
longus. The head is of large size; on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

This bone is known by the single kidney-shaped articular surface on its base, the deeply grooved appearance of the plantar surface of its head, and its great thickness relatively to its length. When it is placed in its natural position, the concave border of the kidney-shaped articular surface on its base points to the side to which the bone belongs.

**Attachment of Muscles.**—To three: part of the Tibialis anticus, the Peroneus longus, and the First dorsal interosseous.

**Second Metatarsal (os metatarsale II).**—The second (Fig. 184) is the longest and largest of the remaining metatarsal bones, being prolonged backward into the recess formed between the three cuneiform bones. Its tarsal extremity is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal lateral surface, for articulation with the internal cunei-
articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform. In addition to these articular surfaces there is occasionally a fifth when this bone articulates with the first metatarsal bone. It is oval in shape, and is situated on the inner side of the shaft near the base.

The facets on the tarsal extremity of the second metatarsal bone serve at once to distinguish it from the rest, and to indicate the foot to which it belongs; there being one facet at the upper angle of the internal surface, and two facets, each subdivided into two parts, on the external surface, pointing to the side to which the bone belongs. The fact that the two posterior subdivisions of these external facets sometimes run into one should not be forgotten.

**Attachment of Muscles.**—To four: the Adductor obliquus hallucis, First and Second dorsal interosseous, and a slip from the tendon of the Tibialis posticus; occasionally also a slip from the Peroneus longus.

**Third Metatarsal (os metatarsale III).**—The third metatarsal (Fig. 185) articulates behind, by means of a triangular smooth surface, with the external cuneiform; on its inner side, by two facets, with the second metatarsal; and on its outer side, by a single facet, with the fourth metatarsal. The latter facet is of circular form and situated at the upper angle of the base.

The third metatarsal is known by its having at its tarsal end two undivided facets on the inner side, and a single facet on the outer. This distinguishes it from the second metatarsal, in which the two facets, found on one side of its tarsal end, are each subdivided into two. The single facet (when the bone is put in its natural position) is on the side to which the bone belongs.

**Attachment of Muscles.**—To five: Adductor obliquus hallucis, Second and Third dorsal, and First plantar interosseous, and a slip from the tendon of the Tibialis posticus.

**Fourth Metatarsal (os metatarsale IV).**—The fourth metatarsal (Fig. 186) is smaller in size than the preceding; its tarsal extremity presents a terminal quad-

---

*Fig. 186.*—The fourth metatarsal. (Left.)

*Fig. 187.*—The fifth metatarsal. (Left.)
metatarsal, and a posterior portion for articulation with the external cuneiform; on the outer side a single facet, for articulation with the fifth metatarsal.

The fourth metatarsal is known by its having a single facet on either side of the tarsal extremity, that on the inner side being divided into two parts. If this subdivision be not recognizable, the fact that its tarsal end is bent somewhat outward will indicate the side to which it belongs.

Attachment of Muscles.—To five: Adductor obliquus hallucis, Third and Fourth dorsal, and Second plantar interosseous, and a slip from the tendon of the Tibialis posterior.

Fifth Metatarsal Bone, or the Metatarsal Bone of the Little Toe (os metatarsale V). —The fifth metatarsal (Fig. 187) is recognized by the tubercle (tuberositas ossis metatarsalis V) on the outer side of its base. It articulates behind, by a triangular surface cut obliquely from without inward, with the cuboid, and internally with the fourth metatarsal.

The projection on the outer side of this bone at its tarsal end at once distinguishes it from the others, and points to the side to which it belongs.

Attachment of Muscles.—To six: the Peroneus brevis, Peroneus tertius, Flexor brevis minimi digiti, Adductor transversus hallucis, Fourth dorsal, and Third plantar interossei.

Articulations.—Each bone articulates with the tarsal bones by one extremity, and by the other with the first row of phalanges. The number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth.

The Phalanges of the Foot (Phalanges Digitorum Pedis).

The phalanges of the foot, both in number and general arrangement, resemble those in the hand; there being two in the great toe and three in each of the other toes. The nutritive foramina correspond to those in the phalanges of the hand.

The first or proximal phalanx (phalanx prima) resembles closely the corresponding bone of the hand. The shaft also is compressed from side to side, convex above, concave below. The posterior extremity is concave; and the anterior extremity presents a trochlear surface, for articulation with the second phalanx.

The second phalanx (phalanx secunda) is remarkably small and short, but rather broader than the first phalanx.

The ungual or distal phalanx (phalanx tertia) in form resembles the bone of the corresponding finger, but is smaller, flattened from above downward, presenting a broad base for articulation with the second phalanx, and an expanded extremity for the support of the nail and end of the toe.

Articulation.—The first row, with the metatarsal bones behind and second phalanges in front; the second row of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row of the four outer toes, with the second phalanges.

Attachment of Muscles.—To the first phalanges. Great toe, five muscles: innermost tendon of Extensor brevis digitorum, Abductor hallucis, Adductor obliquus hallucis, Flexor brevis hallucis, Adductor transversus hallucis. Second toe, three muscles: First and Second dorsal interosseous and First lumbrical. Third toe, three muscles: Third dorsal and First plantar interosseous and Second lumbrical. Fourth toe, three muscles: Fourth dorsal and Second plantar interosseous and Third lumbrical. Fifth toe, four muscles: Flexor brevis minimi digiti, Abductor minimi digiti, and Third plantar interosseous, and Fourth lumbrical.—Second phalanges. Great toe; Extensor longus hallucis, Flexor longus hallucis. Other toes; Flexor brevis digitorum, one slip of the common

tendon of the Extensor longus and brevis digitorum.1—Third phalanges: two slips from the common tendon of the Extensor longus and Extensor brevis digitorum, and the Flexor longus digitorum.

Development of the Foot (Fig. 188).

The Tarsal Bones are each developed by a single centre, excepting the os calcis which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: os calcis, at the sixth month of fetal life; astragalus,

![Diagram of foot development]

Tarsus.
One centre for each bone, except os calcis.

Applies 10th year; unites after puberty.

Metatarsus.
Two centres for each bone:
One for shaft, except os calcis.
One for digital extremity except 1st.

Appears 18th-20th year.
Appears 7th week.

Phalanges. Appear 2nd-4th month.
Two centres for each bone:
One for shaft.
One for metatarsal extremity.

Appears 6th-7th year.
Appears 2nd-4th month.
Appears 7th week.

Unites 17th-18th year.

Fig. 188.—Plan of the development of the foot.

about the seventh month; cuboid, at the ninth month; external cuneiform, during the first year; internal cuneiform in the third year; middle cuneiform and scaphoid in the fourth year. The epiphysis for the posterior tuberosity of the os calcis appears at the tenth year, and unites with the rest of the bone soon after puberty.

The Metatarsal Bones are each developed by two centres: one for the shaft and one for the digital extremity in the four outer metatarsal; one for the shaft and one for the base in the metatarsal bone of the great toe.2 Ossification com-

1 Except the second phalanx of the fifth toe, which receives no slip from the Extensor brevis digitorum.
2 As was noted in the first metacarpal bone, so in the first metatarsal, there is often to be observed a tendency to the formation of a second epiphysis in the distal extremity.
mences in the centre of the shaft about the ninth week, and extends toward either extremity. The centre in the proximal end of the first metatarsal bone appears about the third year, the centre in the distal end of the other bones between the fifth and eighth years; they become joined between the eighteenth and twentieth years.

The Phalanges are developed by two centres for each bone: one for the shaft and one for the metatarsal extremity. The centre for the shaft appears about the tenth week, that for the epiphysis between the fourth and tenth years; they join the shaft about the eighteenth year.

Construction of the Foot as a Whole (Figs. 189, 190).

The foot is constructed on the same principles as the hand, but modified to form a firm basis of support for the rest of the body when in the erect position. It is more solidly constructed, and its component parts are less movable on each other than in the hand. This is especially the case with the great toe, which has to assist in supporting the body, and is therefore constructed with greater solidity; it lies parallel with the other toes, and has a very limited degree of mobility, whereas the thumb, which is occupied in numerous and varied movements, is constructed in such a manner as to permit of great mobility. Its metacarpal bone is directed away from the others, so as to form an acute angle with the second, and it enjoys a considerable range of motion at its articulation with the carpus. The foot is placed at right angles to the leg—a position which is almost peculiar to man, and has relation to the erect position which he maintains. In order to allow of its supporting the weight of the whole body in this position with the least expenditure of material, it is constructed in the form of an arch. This antero-posterior or longitudinal arch is made up of two unequal limbs. The
hinder one, which is made up of the os calcis and the posterior part of the astragalus, is about half the length of the anterior limb, and measures about three inches. The anterior limb consists of the rest of the tarsal and the metatarsal bones, and measures about seven inches. It may be said to consist of two parts, an inner segment made up of the head of the astragalus, the scaphoid, the three cuneiform, and the three inner metatarsal bones; and an outer segment composed of the os calcis, the cuboid, and the two outer metatarsal bones. The summit of the arch is at the superior articular surface of the astragalus; and its two extremities—that is to say, the two piers on which the arch rests in standing—are the tubercles on the under surface of the os calcis posteriorly, and the heads of the metatarsal bones anteriorly. The weakest part of the arch is the joint between the astragalus and scaphoid, and here it is more liable to yield in those who are overweighted, and in those in whom the ligaments which complete and preserve the arch are relaxed. This weak point in the arch is braced on its concave surface by the inferior calcaneo-scaphoid ligament, which is more elastic than most other ligaments, and thus allows the arch to yield from jars or shocks applied to the anterior portion of the foot and quickly restores it to its pristine condition. This ligament is supported internally by blending with the Deltoid ligament, and inferiorly by the tendon of the Tibialis posticus muscle, which is spread out into a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it.

In addition to this longitudinal arch the foot presents a transverse arch, at the anterior part of the tarsus and hinder part of the metatarsus. This, however, can scarcely be described as a true arch, but presents more the character of a half-dome. The inner border of the central portion of the longitudinal arch is elevated from the ground, and from this point the bones arch over to the outer border, which is in contact with the ground, and, assisted by the longitudinal arch, produce a sort of rounded niche on the inner side of the foot, which gives the appearance of a transverse as well as a longitudinal arch.

The line of the foot, from the point of the heel to the toes, is not quite straight, but is directed a little outward, so that the inner border is a little convex and the outer border concave. This disposition of the bones becomes more marked when the longitudinal arch of the foot is lost, as in the disease known under the name of "flat-foot."

Surface Form.—On the dorsum of the foot the individual bones are not to be distinguished with the exception of the head of the astragalus, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole surface forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the scaphoid, the middle cuneiform, and the second metatarsal bones; from this it gradually inclines outward and more rapidly inward. On the inner side of the foot, the internal tuberosity of the os calcis and the ridge separating the inner from the posterior surface of the bone may be felt most posteriorly. In front of this, and below the internal malleolus, may be felt the projection of the sustentaculum tali. Passing forward is the well-marked tuberosity of the scaphoid bone, situated about an inch or an inch and a quarter in front of the internal malleolus. Further toward the front, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the internal sesamoid bone is to be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe are to be felt. On the outer side of the foot the most posterior bony point is the outer tuberosity of the os calcis, with the ridge separating the posterior from the outer surface of the bone. In front of this the greater part of the external surface of the os calcis is subcutaneous; on it, below and in front of the external malleolus, may be felt the peroneal ridge, when this process is present. Farther forward, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx may be defined. The sole of the foot is almost entirely covered by soft parts, so that but few bony parts are to be made out, and these somewhat obscurely. The hinder part of the under surface of the os calcis and the heads of the metatarsal
bones, with the exception of the first, which is concealed by the sesamoid bones, may be recognized.

Surgical Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface and joined together by very strong ligaments, which serve to mitigate the intensity of violence applied to this part of the body. When fracture does occur, these bones, being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence. As the bones have only a very scanty amount of soft parts over them, fractures are very often compound, and amputation is frequently necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group, that is, of the calcaneus and astragalus, are most frequently produced by falls from a height on to the feet; though fracture of the os calcis may be caused by direct violence or by muscular action. The posterior part of the bone, that is, the part behind the articular surfaces, is almost always the seat of the fracture, though some few cases of fracture of the sustentaculum tali and of vertical fracture between the two articulating facets have been recorded. The neck of the astragalus, being the weakest part of the bone, is most frequently fractured, though fractures may occur in any part and almost in any direction, either associated or not with fracture of other bones.

In cases of club-foot, especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is especially the case in congenital equino-varus, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the scaphoid. The tarsal bones are peculiarly liable to become the seat of tuberculous caries, and this condition may arise after comparatively trivial injuries. There are several reasons to account for this. They are composed of a delicate cancellated structure, surrounded by intricate synovial membranes. They are situated at the farthest point from the central organ of the circulation and exposed to vicissitudes of temperature; and, moreover, on their dorsal surface are thinly clad with soft parts which have but a scanty blood-supply. And finally, after slight injuries, they are not maintained in a condition of rest to the same extent as structures suffering from similar injuries in some other parts of the body. Caries of the calcaneus or astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, in consequence of the disease spreading through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the whole or a part of the foot is frequently required either for injury or disease. The principal amputations are as follows: (1) Syme's: amputation at the ankle-joint by a heel-flap, with removal of the malleoli and a thin slice from the lower end of the tibia. (2) Roux's: amputation at the ankle-joint by a large internal flap. (3) Pirogoff's amputation: removal of the whole of the tarsal bones, except the posterior part of the os calcis. A thin slice is sawn from the tibia and fibula, including the two malleoli. The sawn surface of the os calcis is then turned up and united to the similar surface of the tibia. (4) Subastragaloid amputation: removal of the foot below the astragalus through the joint between it and the os calcis. This operation has been modified by Hancock, who leaves the posterior third of the os calcis and turns it up against the denuded surface of the astragalus. This latter operation is of doubtful utility and is rarely performed. (5) Chopart's or medio-tarsal: removal of the anterior part of the foot with all the tarsal bones except the os calcis and astragalus; disarticulation being effected through the astragalo-scaphoid and calcaneo-cuboid joints. (6) Lisfranc's: amputation of the anterior part of the foot through the tarso-metatarsal joints. This was modified by Hey, who disarticulated through the joints of the four outer metatarsal bones with the tarsus, and sawed off the projecting internal cuneiform; and by Skey, who sawed off the base of the second metatarsal bone and disarticulated the others.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus and os calcis for disease limited to the one bone, or again the astragalus may require excision in cases of subastragaloid dislocation, or, as recommended by M.R Lund, in cases of tesserate talipes. The cuboid has been removed for the same reason by Mr. Solly. But the latter two operations have fallen into disuse, and have been superseded by resection of a wedge-shaped piece of bone from the outer side of the tarsus. Finally, Miekulicz and Watson have devised operations for the removal of more extensive portions of the tarsus. Miekulicz's operation consists in the removal of the os calcis and astragalus, along with the articular surfaces of the tibia and fibula, and also of the scaphoid and cuboid. The remaining portion of the tarsus is then brought into contact with the sawn surfaces of the tibia and fibula, and fixed there. The result is a position of the shortened foot resembling talipes equinus. Watson's operation is adapted to those cases where the disease is confined to the anterior tarsal bones. By two lateral incisions he saws through the bases of the metatarsal
bones in front and opens up the joints between the scaphoid and astragalus, and the cuboid and os calcis, and removes the intervening bones.

Fractures of the metatarsal bones and phalanges are nearly always due to direct violence, and in many cases the injury is the result of severe crushing accidents, necessitating amputation. The metatarsal bones, and especially the metatarsal bone of the great toe, are frequently diseased, either in tuberculous subjects or in perforating ulcer of the foot.

Sesamoid Bones (Ossa Sesamoidea) (Figs. 191, 192).

These are small rounded masses, cartilaginous in early life, osseous in the adult, which are developed in those tendons which exert a great amount of pressure upon the parts over which they glide. It is said that they are more commonly found in the male than in the female, and in persons of an active muscular habit than in those who are weak and debilitated. They are invested throughout their whole surface by the fibrous tissue of the tendon in which they are found, excepting upon that side which lies in contact with the part over which they play, where they present a free articular facet. They may be divided into two kinds: those which glide over the articular surfaces of the joints, and those which play over the cartilaginous facets found on the surfaces of certain bones.

The sesamoid bones of the joints in the upper extremity are two on the palmar surface of the metacarpo-phalangeal joint in the thumb, developed in the tendons of the Flexor brevis pollicis; one on the palmar surface of the interphalangeal joint of the thumb; occasionally one or two opposite the metacarpo-phalangeal articulations of the fore and little fingers; and, still more rarely, one opposite the same joints of the third and fourth fingers. In the lower extremity, the patella, which is developed in the tendon of the Quadriceps extensor; two small sesamoid bones, found in the tendons of the flexor brevis hallucis, opposite the metatarso-phalangeal joint of the great toe; one sometimes over the interphalangeal joint of the great toe; and occasionally one in the metatarso-phalangeal joint of the second toe, the little toe, and, still more rarely, the third and fourth toes.
Those found in the tendons which glide over certain bones occupy the following situations: one sometimes found in the tendon of the Biceps cubiti, opposite the tuberosity of the radius; one in the tendon of the Peroneus longus, where it glides through the groove in the cuboid bone; one appears late in life in the tendon of the Tibialis anticus, opposite the smooth facet of the internal cuneiform bone; one is found in the tendon of the Tibialis posticus, opposite the inner side of the head of the astragalus; one in the outer head of the Gastrocnemius, behind the outer condyle of the femur; and one in the conjoined tendon of the Psoas and Iliacus, where it glides over the os pubis. Sesamoid bones are found occasionally in the tendon of the Gluteus maximus, as it passes over the great trochanter, and in the tendons which wind round the inner and outer malleoli.
THE ARTICULATIONS OR JOINTS.

THE various bones of which the Skeleton consists are connected together at different parts of their surfaces, and such a connection is designated by the name of joint or articulation. Arthrology is the branch of anatomy which treats of the joints. If the joint is immovable, as between the cranial and most of the facial bones, the adjacent margins of the bones are applied in almost close contact, a thin layer of fibrous membrane, the sutural ligament, and, at the base of the skull, in certain situations, a thin layer of cartilage, being interposed. Where slight movement is required, combined with great strength, the osseous surfaces are united by tough and elastic fibro-cartilages, as in the joints between the vertebral bodies and interpubic articulations; but in the movable joints the bones forming the articulation are generally expanded for greater convenience of mutual connection, covered by cartilage, held together by strong bands or capsules of fibrous tissue called ligaments, and partially lined by a membrane, the synovial membrane, which secretes a fluid to lubricate the various parts of which the joint is formed; so that the structures which enter into the formation of a joint are bone, cartilage, fibro-cartilage, ligament, and synovial membrane.

Bone.—Bone constitutes the fundamental element of all the joints. In the long bones the extremities are the parts which form the articulations; they are generally somewhat enlarged, consisting of spongy cancellous tissue, with a thin coating of compact substance. In the flat bones the articulations usually take place at the edges, and, in the short bones, at various parts of their surface. The layer of compact bone which forms the articular surface, and to which the cartilage is attached, is called the articular lamella. It is of a white color, extremely dense, and varies in thickness. Its structure differs from ordinary bone-tissue in this respect, that it contains no Haversian canals, and its lacunae are much larger than in ordinary bone and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently more dense and firmer than ordinary bone, and is evidently designed to form a firm, and unyielding support for the articular cartilage.

Cartilage.—Cartilage is material which is a transition stage of connective tissue into bone. When boiled it yields chondrin. - Cartilage is not vascular and is found in various parts of the body; in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, which are to be kept permanently open, such as the air passages, nostrils, and ears. In the foetus in an early period the greater part of the skeleton is cartilaginous. As this cartilage is replaced by bone, it is called temporary in contradistinction to that which remains unossified during life, and which is called permanent. Cartilage is divided into:

1. Hyaline cartilage.
2. Elastic cartilage.
3. Fibro-cartilage.

Hyaline Cartilage.—This structure is found in the nose, larynx, trachea, bronchi, and in symphyses and synchondroses; costal cartilage and epiphyseal cartilage are composed of it, and as articular cartilage (cartilago articularis) it covers joint

(259)
surfaces. It is a bluish or pearly hued substance, in reality a modified connective tissue, but much harder than most connective tissues. The investing membrane, the perichondrium, is composed of two layers: an outer fibrous layer which carries blood-vessels and an inner or chondrogenetic layer, which contains cartilage-forming cells (chondroblasts).

Cartilage does not contain blood-vessels except in regions of very active growth or of ossification. In such regions vessels may be formed. Hyaline cartilage is composed of round or oval cells and intercellular substance. Each cell contains granular protoplasm and a nucleus, and the nucleus contains one or two nucleoli. The cells are placed in the so-called cartilage spaces of the ground substance, and the ground substance immediately surrounding a space is called a cartilage capsule. The cells are placed in groups and near the surface are arranged in rows, and in some regions are flattened by pressure. The intercellular or ground substance (matrix) is an apparently homogeneous and structureless material between the cartilage spaces. By certain methods, however, fibres can be demonstrated in it. These fibrils in general are parallel. In some of the lower animals canals have been demonstrated. In man it has not been proved that canals exist, and it has been suggested that the fibrils act as paths of conduction for nutritive fluid.

Articular cartilage forms a thin incrustation upon the joint-surfaces of the bones, and its elasticity enables it to break the force of any concussion, while its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, where the greatest pressure is received; and the reverse is the case on the concave articular surfaces. Articular cartilage appears to derive its nutriment partly from the vessels of the neighboring synovial membrane, partly from those of the bone upon which it is implanted. 'Toybees has shown that the minute vessel of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by the salts of lime without any appearance of true bone. The process of calcification occurs also, and still more frequently, according to Rollett, in such cartilages as those of the trachea and in the costal cartilages, which are prone afterward to conversion into true bone.

Elastic Cartilage.—In this structure there are elastic fibres in the matrix, which fibres at the periphery of the cartilage enter into the perichondrium. Such cartilage is not blue-white in color, but is a very light yellow, and is not to be regarded as identical with elastic fibrous tissue. Elastic cartilage is found in the epiglottis and the cartilages of the larynx.

Fibro-cartilage is composed of white fibrous tissue and cartilage in varying proportions; it is to the first of these two constituents that its flexibility and toughness are chiefly owing, and to the latter its elasticity; the cells are fewer in number, but are possessed of more definite capsules than those of hyaline cartilage, and they are usually arranged in groups surrounded by small islands of hyaline matrix, which may be concentrically striated. The hyaline islands are separated from one another by bundles of white fibrous tissue that pursue a markedly wavy course.

Fibro-cartilage is found at the point of insertion of the ligamentum teres into the head of the femur, in the intervertebral disks, in the pubic symphysis, and in the interarticular cartilages.

The fibro-cartilages admit of arrangement into four groups: interarticular, connecting, circumferential, and stratiform.

1. The interarticular fibro-cartilages (menisci) are flattened, fibro-cartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the
articular cartilages of certain joints. They are free on both surfaces, thinner toward their centre than at their circumference, and held in position by the attachment of their margins and extremities to the surrounding ligaments. The synovial membrane of the joint is prolonged over them a short distance from their attached margins. They are found in the temporo-mandibular, sterno-clavicular, acromioclavicular, wrist- and knee-joints. These cartilages are usually found in those joints which are most exposed to violent concussion and subject to frequent movement. Their use is to maintain the apposition of the opposed surfaces in their various motions; to increase the depth of the articular surfaces and give ease to the gliding movement; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these interarticular fibro-cartilages serve an important purpose in increasing the variety of movements in a joint. Thus, in the knee-joint there are two kinds of motion—viz., angular movement and rotation—although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the interarticular cartilage, the latter between the cartilage and the head of the tibia. So, also, in the temporo-mandibular joint, the upward and downward movement of opening and shutting the mouth takes place between the fibro-cartilage and the jaw-bone, the grinding movement between the glenoid cavity and the fibro-cartilage, the latter moving with the jaw-bone.

Intercarticular cartilages may divide the joint into two distinct cavities, as in the temporo-maxillary articulation. The periphery of an articular cartilage is attached particularly to the capsule and may also be attached to the non-articular portion of the bone. The semilunar cartilages of the knee resemble tendon more than they do cartilage. The fibres are arranged in dense, more or less parallel bundles, separated by small, scattered hyaline cells, and the disks are attached to the bone by thin layers of hyaline cartilage.

2. The connecting fibro-cartilages are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebrae and between the pubic bones. They form disks which adhere closely to both of the opposed surfaces, and are composed of concentric rings of fibrous tissue, with cartilaginous lamina interposed, the former tissue predominating toward the circumference, the latter toward the centre.

3. The circumferential fibro-cartilages consist of a rim of fibro-cartilage, which surrounds the margin of some of the articular cavities, as the cotyloid cavity of the hip and the glenoid cavity of the shoulder; they serve to deepen the articular surface, and to protect its edges.

4. The stratiform fibro-cartilages are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibro-cartilages are developed also in the tendons of some muscles, where they glide over bones, as in tendons of the Peroneus longus and the Tibialis posterior.

Ligaments.—Ligaments consist of bands of various forms, serving to connect together the articular extremities of bones, and are composed mainly of coarse bundles of very dense white fibrous tissue placed parallel with, or closely interlaced with, one another, and presenting a white, shining, silvery aspect. These bundles are called fasciculi. They are held together by a cement substance containing cells which resemble those of tendon. A ligament is pliant and flexible, so as to allow of the most perfect freedom of movement, but it is strong, tough, and inextensile, so as not readily to yield under the most severely applied force; it is consequently well adapted to serve as the connecting medium between the bones. Some ligaments consist entirely of yellow elastic tissue (elastic fibrous tissue), the elastic fibres branching considerably, but maintaining in general a parallel course. The fibres are in bundles, between which
areolar connective tissue lies. The ligamenta subflava, which connect together the adjacent arches of the vertebrae in man and the ligamentum nuchae in the lower animals are composed of yellow elastic tissue. In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

**Synovial Membranes.**—These membranes are serous in character. A synovial membrane consists of loose connecting tissue (subendothelial tissue), containing fat, vessels, and nerves, its inner surface being lined with a single layer of flat endothelial cells. The endothelial cells are polyhedral, and each cell possesses a flattened oval nucleus. The cells are held together by intercellular cement. It is believed by some that little openings occur at intervals in the intercellular cement, but it is held by many that the supposed openings are artifacts. Synovial cavities contain a little fluid. A non-articular synovial membrane does not actually secrete fluid, but it is moistened by lymph which passes through the membrane and into the cavity by osmosis.

Joint cavities and bursa communicating with joints contain a characteristic fluid which is a secretion of the membrane. It is yellowish-white or slightly red-dish, somewhat cloudy, viscid like the white of an egg, having a strongly alkaline reaction and a slightly saline taste. It consists of fats, salts, albumins, extractives from lymph, a mucinous body known as synovin,¹ and another mucin-like body, which is rich in phosphorus (Simon). The nature of synovin is uncertain, but it is neither a nucleo-albumin nor a mucin (Simon). The second mucin-like body is probably a nucleo-albumin (Simon). The quantitative composition of synovial fluid varies with motion and rest (Frerichs, Simon). During exercise the mucin-like bodies, the albumins, and the extractives increase, and the salts and water diminish.² The synovial membranes found in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

**Articular Synovial Membrane.**—Articular synovial membrane is found in every freely movable joint. It lines the capsule of the joint and is reflected upon the non-articular intracapsular portion of the bones which enter into the formation of the joint. In the fetus this membrane is said, by Toynbee, to be continued over the surface of the cartilages; but in the adult it merely encroaches for a short distance upon the margins of the cartilages, to which it is firmly attached; it then invests the inner surface of the capsular or other ligaments enclosing the joint, and is reflected over the surface of any tendons passing through its cavity, as the tendon of the Popliteus in the knee and the tendon of the Biceps in the shoulder. Hence the articular synovial membrane may be regarded as a short wide tube, attached by its open ends to the margins of the articular cartilages, and covering the inner surface of the various ligaments which connect the articular surfaces, so that along with the cartilages it completely encloses the joint-cavity. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called synovial ligaments, and are especially distinct in the knee. In some joints there are flattened folds, subdivided at their margins into fringe-like processes (synovial villi), the vessels of which have a convoluted arrangement. These latter generally project from the synovial membrane near the margin of the cartilage and lie flat upon its surface. They consist of connective tissue covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. The larger folds often contain considerable quantities of fat. They were described by Clopton Havers as mucilaginous glands, and as the source of the synovial secretion. Under certain diseased conditions similar processes are found covering the entire surface of the synovial membrane, forming a

¹ Simon's Physiological Chemistry.
² Frerichs' analysis, in Simon's Physiological Chemistry.
mass of pedunculated fibro-fatty growths which project into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

**Bursal Synovial Membrane.**—The bursal synovial membranes are sacs interposed between surfaces which move upon each other, producing friction, as in the gliding of a tendon or of the integument over projecting bony surfaces. There are two groups of synovial bursae designated according to situation: 1. Those situated between the integument and a prominent process of bone. Such a bursa is called a *subcutaneous synovial bursa* (*bursa mucosa subcutanea*) (Fig. 246). Subcutaneous bursae are found between the integument and the front of the patella, over the olecranon, the malleoli, and other prominent parts. 2. Those situated between tendons or muscles and the bony or cartilaginous surfaces over which the tendons or muscles glide (Figs. 193 and 194). Such a bursa is called a

**Fig. 193.**—Scheme of a serous bursa. (Polier and Charpy.)

**Fig. 194.**—Scheme of a serous bursa. (Polier and Charpy.)

**Subtendinous synovial bursa** (*bursa mucosa subtendinea*). For example, a bursa is placed between the Glutei muscles and the surface of the great trochanter. Subtendinous bursae are found often about joints and not unusually communicate directly with the cavity of the joint by means of an opening in the joint capsule, the synovial membrane of the joint being continuous with the synovial membrane of the bursa. For instance, the bursa between the tendon of the Psoas and Iliacus muscles and the capsular ligament of the hip communicates with the hip-joint; and the bursa between the under surface of the Subscapularis muscle and the neck of the scapula communicates with the shoulder-joint. Bursae consist of a thin wall of connective tissue, partially covered by patches of cells, and contain a viscid fluid.

**Vaginal Synovial Membrane** (Fig. 326).—A vaginal synovial membrane (*synovial sheath, thecal synovial bursa, vagina mucosa tendinis*) serves to facilitate the gliding of a tendon in the osseo-fibrous canal through which it passes. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the contained tendon, the space between the two free surfaces of the membrane containing synovia. These sheaths are chiefly found surrounding the tendons of the Flexor and Extensor muscles of the fingers and toes as they pass through the osseo-fibrous canals in the hand or foot. A vaginal sheath covers the long head of the biceps muscle from its origin to the surgical neck of the humerus (Fig. 222).

**Pads of adipose tissue** (*synovial fat pads*) are found in certain joints between the synovial membrane and the surface beneath it. These pads fill up certain joint intervals, and by adapting themselves to changes of position maintain the form of the joint during movement.

The articulations are divided into three classes: *synarthrosis*, or immovable; *amphiarthrosis*, or mixed; and *diarthrosis*, or movable joints.
Synarthrosis (Immovable Articulation).

Synarthrosis includes all those articulations in which the surfaces of the bones are in almost direct contact, being fastened together by an intervening mass of connective tissue, and in which there is no joint cavity and no appreciable motion. Examples of synarthrosis are the joints between the bones of the cranium and of the face, excepting those of the lower jaw. The varieties of synarthrosis are four in number: sutura, schindylesis, gomphosis, and synchondrosis.

Sutura.—Sutura (a seam) is that form of articulation met with only in the skull, where the contiguous margins of flat bones are apparently but not really in immediate contact, a thin layer of fibrous tissue, sutural membrane, being interposed. This membrane is continuous externally with the pericranium and internally with the dura mater. In some of the sutures the sutural membrane gradually disappears as age advances and the two bones form an osseous fusion. Where the articulating surfaces are connected by a series of processes and indentations interlocked together, it is termed a true suture or sutura vera, of which there are three varieties: sutura dentata, serrata, and limbosa. The sutura dentata (dens, a tooth) is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the sutura serrata (serra, a saw) the edges of the two bones forming the articulation are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the sutura limbosa (limbus, a selvage), besides the dentated processes, there is a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed the false suture (sutura notha), of which there are two kinds: the sutura squamosa (squama, a scale), formed by the overlapping of two contiguous bones by broad bevelled margins, as in the squamo-parietal (squamous) suture; and the sutura harmonia (ἁμορνία, a joining together), where there is simple apposition of two contiguous, rough, bony surfaces, as in the articulation between the two superior maxillary bones or of the horizontal plates of the palate bones.

Schindylesis.—Schindylesis (σχίνδυλης, a fissure) is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminae in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the superior maxillary and palate bones.

Gomphosis.—Gomphosis (γόμφος, a nail) is an articulation formed by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulation of the teeth with the alveoli of the maxillary bones.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a synchondrosis. This is a temporary form of joint, because the hyaline cartilage becomes converted into bone before adult life. Such a joint is found between the epiphyses and shafts of long bones. Another example of a synchondrosis is the occipito-sphenoid articulation.

Amphiarthrosis (Mixed Articulation).

In this form of articulation the contiguous osseous surfaces may be connected together by broad flattened disks of fibro-cartilage, of a more or less complex structure, which adhere to the end of each bone, as in the articulation between the bodies of the vertebrae and the pubic symphyses. This is termed symphysis. In a symphysis there is a partial joint cavity which may exhibit an incomplete synovial membrane. Each constituent bone is coated with hyaline cartilage and
the bones are held together by ligaments and intervening fibro-cartilage. The bony surfaces of an amphiarthrodial joint may be united by an interosseous ligament, as in the inferior tibio-fibular articulation. To such an articulation the term *syndesmosis* is applied. A mixed articulation permits limited motion.

**Diarthrosis (Movable Articulation).**

This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing character. They are formed by the approximation of two contiguous bony surfaces covered with cartilage, connected by ligaments and lined by synovial membrane. The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one form, the *ginglymus* or *hinge-joint*, this axis is, practically speaking, transverse; in the other, the *trochoid* or *pivot-joint*, it is longitudinal. There are two varieties where the movement is biaxial or around two horizontal axes at right angles to each other or at any intervening axis between the two. These are the *condyloid-joint* and the *saddle-joint*. There is one form of joint where the movement is polyaxial, the *enarthrosis* or *ball-and-socket joint*. And finally there are the *arthrodia* or *gliding joints*. In a diarthrosis there is always a joint cavity lined with synovial membrane—the articular surfaces of the bones are covered with hyaline cartilage and the bones are held in contact by ligaments.

**Ginglymus or Hinge-joint** (*γίγλιμος*, a hinge).—In this form of joint the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forward and backward; the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone, and there is always a certain amount of alteration from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The most perfect forms of ginglymus are the interphalangeal joints and the joint between the humerus and ulna; the knee and ankle are less perfect, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

**Trochoid or Pivot-joint or Rotary-joint.**—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or the ring on the pivot, the ring being formed partly of bone, partly of ligament. In the superior radio-ulnar articulation the ring is formed partly by the lesser sigmoid cavity of the ulna; in the rest of its extent, by the orbicular ligament; here the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas the ring is formed in front by the anterior arch of the atlas; behind, by the transverse ligament; here the ring rotates round the odontoid process.

**Condyloid or Biaxial Articulation.**—In this form of joint an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion and extension, adduction and abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. An example of this form of joint is found in the wrist.

**Articulation by Reciprocal Reception or Saddle-joint.**—In this variety the articular surfaces are concavo-convex; that is to say, they are inversely convex in one direction and concave in the other. The movements are the same as in the preceding form; that is to say, there is flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The articular surfaces are connected
by a capsular ligament. The best example of this form of joint is the carpo-
metacarpal joint of the thumb.

**Enarthrosis**, or Ball-and-socket-joint, is that form of joint in which the distal
bone is capable of motion around an indefinite number of axes which have one
common centre. It is formed by the reception of a globular head into a deep
cup-like cavity (hence the name “ball-and-socket”), the parts being kept in
apposition by a capsular ligament strengthened by accessory ligamentous bands.
Examples of this form of articulation are found in the hip and shoulder.

**Arthrodia.**—Arthrodia is that form of joint which admits of a gliding move-
ment; it is formed by the approximation of plane surfaces or one slightly concave,
the other slightly convex, the amount of motion between them being limited by
the ligaments, or osseous processes, surrounding the articulation; as in the articu-
lar processes of the vertebrae, the carpal joints, except that of the os magnum
with the scaphoid and semilunar bones, and the tarsal joints with the exception
of the joint between the astragalus and the scaphoid.

Below, in tabular form, are the names, distinctive characters, and examples
of the different kinds of articulations.

**The Kinds of Movement Admitted in Joints.**

The movements admissible in joints may be divided into four kinds: gliding,
angular movement, circumduction, and rotation. These movements are often,
however, more or less combined in the various joints, so as to produce an infinite
variety, and it is seldom that we find only one kind of motion in any particular joint.

\[ \text{**Dentata**, having tooth-like processes.} \]
\[ \text{As in interparietal suture.} \]
\[ \text{**Serrata**, having serrated edges like the teeth of a saw.} \]
\[ \text{As in interfrontal suture.} \]
\[ \text{**Limbosa**, having bevelled margins and dentated processes.} \]
\[ \text{As in fronto-parietal suture.} \]
\[ \text{**Squamosa**, formed by thin bevelled margins, overlapping each other.} \]
\[ \text{As in squamo-parietal suture.} \]
\[ \text{**Harmonia**, formed by the apposition of contiguous rough surfaces.} \]
\[ \text{As in intermaxillary suture.} \]

**Synarthrosis**, or Immovable Joint. Surfaces separated by fibrous mem-
brane or by line of cartilage, without any intervening synovial cavity, and im-
movably connected with each other.

As in joints of cranium and face (except lower jaw).

\[ \text{**Sutura vera** (true), articulate by indented borders.} \]
\[ \text{**Sutura**. Articulation by processes and indentations interlocked together.} \]
\[ \text{**Sutura notha** (false), articulate by rough surfaces.} \]

**Schindylesis.**—Articulation formed by the reception of a thin plate of one bone into a fissure of another.
As in articulation of rostrum of sphenoid with vomer.
**Gomphosis.**—Articulation formed by the insertion of a conical process into a socket: the teeth.
Amphiarthrosis, Mixed Articulation.

Symphysis.—Surfaces connected by fibro-cartilage. There is a partial joint cavity and may be an incomplete synovial membrane. Has limited motion. As in joints between bodies of vertebrae.

Syndesmosis.—Surfaces united by an interosseous ligament. As in the inferior tibio-fibular articulation.

Ginglymus.—Hinge-joint; motion limited to two directions, forward and backward. Articular surfaces fitted together so as to permit of movement in one plane. As in the interphalangeal joints and the joint between the humerus and the ulna.

Trochoidea, or Pivot-joint.—Articulation by a pivot process turning within a ring or ring around a pivot. As in superior radio-ulnar articulation and atlanto-axial joint.

Condyloid.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation. As the wrist-joint.

Reciprocal Reception (saddle-joint).—Articular surfaces inversely convex in one direction and concave in the other. Movement in every direction except axial rotation. As in the carpo-metacarpal joint of the thumb.

Enarthrosis.—Ball-and-socket joint; capable of motion in all directions. Articulations by a globular head received into a cup-like cavity. As in hip- and shoulder-joints.

Arthrodia.—Gliding joint; articulations by plane surfaces, which glide upon each other. As in carpal and tarsal articulations.

Gliding movement is the most simple kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints, but in some, as in the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form, limited by the ligaments which enclose the articulation. Gliding over a wide range, as is seen in the sliding of the patella over the femur, is called coaptation.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place in four directions: forward and backward, constituting flexion or bending and extension or straightening, or inward toward and outward from the mesial line of the body, constituting adduction and abduction. Abduction of a limb is movement away from the mesial line of the body. Adduction of a limb is movement toward the mesial line of the body. In the fingers and toes the significance of the terms are different; abduction means movement of the fingers away from the middle finger or of the toes away from the second toe; adduction means movement of fingers toward the middle finger or of the toes toward the second toe. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip-, shoulder-, and metacarpal-joint of the thumb, and partially in the wrist. When two anterior surfaces are brought nearer together, as by bending the elbow or wrist, we speak of the movement as ventral, anterior, or palmar flexion. If two posterior surfaces are brought nearer together, as by bending the knee or wrist, we speak of the movement as posterior or dorsal flexion.
At the wrist-joint the bending of the ulnar margin of the hand toward the ulnar side of the forearm is **ulnar flexion**; the bending of the radial margin of the hand toward the radial side of the forearm is **radial flexion**.

**Circumduction** is that limited degree of motion which takes place between the head of the bone and its articular cavity, whilst the extremity and sides of the limb are made to circumscribe a conical space, the base of which corresponds with the inferior extremity of the limb, the apex with the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

**Rotation** is the movement of a bone upon an axis, which is the axis of the pivot on which the bone turns, as in the articulation between the atlas and axis, when the odontoid process serves as a pivot around which the atlas turns; or else is the axis of a pivot-like process which turns within a ring, as in the rotation of the radius upon the humerus.

**Ligamentous Action of Muscles.**—The movements of the different joints of a limb are combined by means of the long muscles which pass over more than one joint, and which, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other, these latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed, so as to bring their attachments nearer together. The uses of this arrangement are threefold: 1. It co-ordinates the kinds of movement which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. "Thus in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended," in consequence of the passage of the Biceps and Triceps cubiti over both joints. 2. It enables the short muscles which pass over only one joint to act upon more than one. "Thus, if the Rectus femoris remain tonically of such length that, when stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes not only an extensor of the hip, but an extensor of the knee as well." 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. "Taxed beyond its strength, a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighboring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of movement, the muscles adapting themselves tonically to the length required." The quotations are from a very interesting paper by Dr. Cleland in the Journal of Anatomy and Physiology, No. 1, 1866, p. 85; by whom I believe this important fact in the mechanism of joints was first clearly pointed out, though it has been independently observed afterward by other anatomists. Dr. W. W. Keen points out how important it is "that the surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist after Colles's fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed, as in 'making a fist,' flexion at the wrist is quickly limited to from 40 to 50 degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed." Dr. Keen further points out that "a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence they can go to sleep and not fall off the perch.'
ARTICULATIONS OF THE VERTEBRAL COLUMN

The articulations may be arranged into those of the trunk, those of the upper extremity, and those of the lower extremity.

ARTICULATIONS OF THE TRUNK.

These may be divided into the following groups, viz.:

I. Of the vertebral column.
II. Of the atlas with the axis.
III. Of the atlas with the occipital bone.
IV. Of the axis with the occipital bone.
V. Of the lower jaw.
VI. Of the ribs with the vertebrae.

VII. Of the cartilages of the ribs with the sternum and with each other.
VIII. Of the sternum.
IX. Of the vertebral column with the pelvis.
X. Of the pelvis.

I. Articulations of the Vertebral Column.

The different segments of the spine are connected together by spinal ligaments (ligamenta columnae vertebrae), which may be divided into five sets: 1. Those connecting the bodies of the vertebrae. 2. Those connecting the laminae. 3. Those connecting the articular processes. 4. Those connecting the spinous processes. 5. Those of the transverse processes.

The articulations of the bodies of the vertebrae with each other form a series of amphiarthrodial joints; those between the articular processes form a series of arthrodial joints.

1. THE LIGAMENTS OF THE VERTEBRAL BODIES OR CENTRA (INTERCENTRAL LIGAMENTS).

Anterior Common Ligament (anterior longitudinal ligament).
Posterior Common Ligament (posterior longitudinal ligament).
Intervertebral Substance (intervertebral disk, fibro-cartilage).

The Anterior Common or Anterior Longitudinal Ligament (ligamentum longitudinale anterius) (Figs. 197, 199, and 203) is a broad and strong band of longitudinal fibres which extends along the anterior (central) surface of the bodies of the vertebrae from the axis to the sacrum. It is broader below than above, thicker in the dorsal than in the cervical or lumbar regions, and somewhat thicker opposite the front of the body of each vertebra than opposite the intervertebral substance. It is attached, above, to the body of the axis by a pointed process, where it is continuous with the anterior atlanto-axial ligament, is connected with the tendon of insertion of the Longus colli muscle, and extends down as far as the upper bone of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral substance and the prominent margins of the vertebrae, but less closely to the middle of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on their front surface and to make the anterior surface of the spine more even. This ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial or longest fibres extend between four or five vertebrae. A second subjacent set extends between two or three vertebrae, whilst a third set, the shortest and deepest, extends from one vertebra to the next. At the side of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by large oval apertures for the passage of vessels.
The **Posterior Common** or **Posterior Longitudinal Ligament** (*ligamentum longitudinale posterius*) (Figs. 195, 197, 202, and 203) is situated within the spinal canal, and extends along the posterior (*dorsal*) surface of the bodies of the vertebrae from the body of the axis above, where it is continuous with the posterior occipito-axial ligament, to the sacrum below. It can be separated from the posterior occipito-axial ligament, as is shown in Fig. 203, and may be regarded as really arising from the clivus. It is broader above than below, and thicker in the dorsal than in the cervical or lumbar regions. In the situation of the intervertebral substance and contiguous margins of the vertebrae, where the ligament is more intimately adherent, it is broad, and presents a series of dentations with intervening concave margins; but it is narrow and thick over the centre of the bodies, from which it is separated by the venæ basis vertebrae. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and formed of a superficial layer occupying the interval between three or four vertebrae, and of a deeper layer which extends between one vertebra and the next adjacent to it. It is separated from the dura mater of the spinal cord by some loose connective tissue, which is very liable to serious infiltration.

The **Intervertebral Fibro-cartilages, Disks, or Substances** (*fibrocartilagines intervertebrales*) (Figs. 196 and 197)—Each fibrocartilaginous disk is of lenticular form and of composite structure. The disks are interposed between the adjacent surfaces of the bodies of the vertebrae from the axis to the sacrum, and form the chief bonds of connection between those bones. In young children intervertebral substance exists in the coccyx. These disks vary in shape, size, and thickness in different parts of the spine. In *shape* they accurately correspond with the surfaces of the bodies between which they are placed, being oval in the cervical and lumbar regions, and circular in the dorsal. Their *size* is greatest in the lumbar region. In *thickness* they vary not only in the different regions of the spine, but in different parts of the same disk: thus, they are thicker in front than behind in the cervical and lumbar regions, while they are uniformly thick in the dorsal region. The intervertebral disks form about one-fourth of the spinal column, exclusive of the first two vertebrae; they are not equally distributed, however, between the various bones; the dorsal portion of the spine
having, in proportion to its length, a much smaller quantity than in the cervical and lumbar regions, which necessarily gives to the latter parts greater pliancy and freedom of movement. The intervertebral disks are adherent, by their surfaces, to a thin layer of hyaline cartilage which covers the upper and under surfaces of the bodies of the vertebrae, and in which, in early life, the epiphysial plate develops, and by their circumference are closely connected in front to the anterior, and behind to the posterior common ligament; whilst in the dorsal region they are connected laterally, by means of the interarticular ligament, to the heads of those ribs which articulate with two vertebrae; they, consequently, form part of the articular cavities in which the heads of these bones are received.

**Structure of the Intervertebral Substance.**—The outer portion of the intervertebral substance is composed of many layers of fibrous connective tissue. This enveloping portion is called the *annulus fibrosus*. The central portion of the disk is composed of soft, pulpy, highly elastic fibro-cartilage, containing some bands of connective tissue. It is called the *nucleus pulposus*, is of a yellowish color, and rises up considerably above the surrounding level when the disk is divided horizontally. This pulpy substance, which is especially well developed in the lumbar region, is the remains of the chorda dorsalis, and, according to Luschka, contains a small synovial cavity in its centre. The outer layers of the disk are arranged concentrically one within the other, the outermost consisting of ordinary fibrous tissue, but the others and more numerous consisting of white fibro-cartilage. These plates are not quite vertical in their direction, those near the circumference being curved outward and closely approximated; whilst those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each plate is composed are directed, for the most part, obliquely from above downward, the fibres of adjacent plates passing in opposite directions and varying in every layer; so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each disk. The pulpy substance presents no concentric arrangement, and consists of a fine fibrous matrix, containing angular cells, united to form a
reticular structure. J. Bland Sutton calls attention to the fact that in the human foetus a transverse ligamentous band crosses the dorsal aspect of the intervertebral disk and is continuous with the interosseous ligaments of the heads of the ribs; and also that a foetal ligamentous band exists in the ventral surface of the intervertebral disk which, after development, becomes the middle fasciculus of the stellate ligament. These bands are named by Sutton the posterior conjugal ligaments and the anterior conjugal ligaments.

*Interneural Articulations* include the ligaments of the laminae; articular processes, spinous processes, and transverse processes.

2. **Ligaments connecting the Laminae.**

Ligamenta Subflava.

The Ligamenta Subflava (*ligamenta flava, ligamenta intercrluralia*) (Figs. 197 and 198) are interposed between the laminae of the vertebrae, from the axis to the sacrum. They are most distinct when seen from the interior of the spinal canal; when viewed from the outer surface they appear short, being overlapped by the laminae. Each ligamentum subflavum consists of two lateral portions, which commence on each side at the root of either articular process, and pass backward to the point where the lamina converge to form the spinous process, where their margins are in contact and to a certain extent united; slight intervals being left for the passage of small vessels. These ligaments consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the lamina above, some distance from its inferior margin, and to the posterior surface, as well as to the margin of the lamina below. In the cervical region they are thin in texture, but very broad and long; they become thicker in the dorsal region, and in the lumbar acquire very considerable thickness. Their highly elastic property serves to preserve the upright posture and to assist in resuming it after the spine has been flexed. These ligaments do not exist between the occiput and atlas or between the atlas and axis.

3. **Ligaments connecting the Articular Processes.**

Capsular Ligaments.

The Capsular Ligaments (*capsulae articulares*) (Fig. 198) are thin and loose ligamentous sacs, attached to the contiguous margins of the articulating processes of each vertebra through the greater part of their circumference, and completed internally by the ligamenta

---

subflava. They are longer and looser in the cervical than in the dorsal or lumbar regions. The capsular ligaments are lined on their inner surface by synovial membrane.

4. Ligaments connecting the Spinous Processes.

Supraspinous Ligament. Interspinous Ligaments.

The **Supraspinous Ligament** (ligamentum supraspinale) (Fig. 197) is a strong fibrous cord, which connects together the apices of the spinous processes from the seventh cervical to the spinous processes of the sacrum. It is thicker and broader in the lumbar than in the dorsal region, and intimately blended, in both situations, with the neighboring aponeurosis. The most superficial fibres of this ligament connect three or four vertebrae; those deeper-seated pass between two or three vertebrae; whilst the deepest connect the contiguous extremities of neighboring vertebrae. It is continued upward to the external occipital protuberance as the **ligamentum nuchae**, which, in the human subject, is thin and forms merely an intermuscular septum.

The **Interspinous Ligaments** (ligamenta interspinalia) (Fig. 197), thin and membranous, are interposed between the spinous processes. Each ligament extends from the root to the summit of each spinous process and connects together their adjacent margins. They meet the ligamenta subflava in front and the supraspinous ligament behind. They are narrow and elongated in the dorsal region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

5. Ligaments connecting the Transverse Processes.

Intertransverse Ligaments.

The **Intertransverse Ligaments** (ligamenta intertransversaria) (Fig. 210) consist of bundles of fibres interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the dorsal, they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

**Actions.** The movements permitted in the spinal column are, flexion, extension, lateral movement, circumduction, and rotation.

In **flexion** (forward flexion), or movement of the spine forward, the anterior common ligament is relaxed, and the intervertebral substances are compressed in front, while the posterior common ligament, the ligamenta subflava, and the inter- and supra-spinous ligaments are stretched, as well as the posterior fibres of the intervertebral disks. The interspaces between the laminae are widened, and the inferior articular processes of the vertebrae above glide upward upon the articular processes of the vertebrae below. Flexion is the most extensive of all the movements of the spine.

In **extension** (backward flexion), or movement of the spine backward, an exactly opposite disposition of the parts takes place. This movement is not extensive, being limited by the anterior common ligament and by the approximation of the spinous processes.

Flexion and extension are free in the lower part of the lumbar region between the third and fourth and fourth and fifth lumbar vertebrae; above the third they are much diminished, and reach their minimum in the middle and upper part of the back. They increase again in the neck, the capability of motion backward from the upright position being in this region greater than that of the motion forward, whereas in the lumbar region the reverse is the case.

In **lateral flexion**, the sides of the intervertebral disks are compressed, the extent of motion being limited by the resistance offered by the surrounding ligamenta.
ments and by the approximation of the transverse processes. This movement may take place in any part of the spine, but is most free in the neck and loins.

Circumduction is very limited, and is produced merely by a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral substances; this, although only slight between any two vertebrae, produces a considerable extent of movement when it takes place in the whole length of the spine, the front of the upper part of the column being turned to one or the other side. This movement takes place only to a slight extent in the neck, but is freer in the upper part of the dorsal region, and is altogether absent in the lumbar region.

It is thus seen that the cervical region enjoys the greatest extent of each variety of movement, flexion and extension especially being very free. In the dorsal region the three movements of flexion, extension, and circumduction are permitted only to a slight extent, while rotation is very free in the upper part and ceases below. In the lumbar region there is free flexion, extension, and lateral movement, but no rotation.

As Sir George Humphry has pointed out, the movements permitted are mainly due to the shape and position of the articulating processes. In the loins the inferior articulating processes are turned outward and are embraced by the superior; this renders rotation in this region of the spine impossible, while there is nothing to prevent a sliding upward and downward of the surfaces on each other, so as to allow of flexion and extension. In the dorsal region, on the other hand, the articulating processes, by their direction and mutual adaptation, especially at the upper part of the series, permit of rotation, but prevent extension and flexion, while in the cervical region the greater obliquity and lateral slant of the articular processes allow not only flexion and extension, but also rotation.

The principal muscles which produce flexion are the Stermo-mastoid, Rectus capitis anticus major, and Longus colli; the Scaleni; the abdominal muscles and the Psoas magnus. Extension is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinalis dorsi et colli, and the Multifidus spinae. Lateral motion is produced by the fourth layer of the muscles of the back, by the Splenius and the Scaleni, the muscles of one side only acting; and rotation by the action of the following muscles of one side only—viz. the Sterno-mastoid, the Rectus capitis anticus major, the Scaleni, the Multifidus spinae, the Complexus, and the abdominal muscles.

II. Articulation of the Atlas with the Axis (Articulatio Atlantoepistrophica).

The articulation of the atlas with the axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed between the anterior arch of the atlas and the transverse ligament (see Fig. 201). Here there are two joints: one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process, the **atlanto-odontoid joint of Cruveilhier**; the other between the anterior surface of the transverse ligament and the back of the process, the **syndesmo-odontoid joint**. Between the articular processes of the two bones there is a double arthrodaia or gliding joint. The ligaments which connect these bones are the

Anterior Atlanto-axial. Transverse.
Posterior Atlanto-axial. Two Capsular.

The **Anterior Atlanto-axial** or the **Anterior Atlo-axoid Ligament** (Figs. 199 and 203) is a strong, membranous layer, attached, above, to the lower border of the anterior arch of the atlas; below, to the base of the odontoid process and to the front of
the body of the axis. It is strengthened in the middle line by a rounded cord, which is attached, above, to the tubercle on the anterior arch of the atlas, and below to the body of the axis, being a continuation upward of the anterior common ligament of the spine. Some anatomists regard this ligament as being a part of the anterior common ligament. The ligament is in relation, in front, with the Recti antici majores.

The Posterior Atlanto-axial or the Posterior Atlo-axoid Ligament (Figs. 200 and 203) is a broad and thin membranous layer, attached, above, to the lower border of the posterior arch of the atlas; below, to the upper edge of the laminae of the axis. This ligament supplies the place of the ligamenta subflava, and is in relation, behind, with the Inferior oblique muscles.

The Transverse Ligament of the Atlas¹ (ligamentum transversum atlantis) (Figs. 201, 202, and 203) is a thick, strong band, which arches across the ring of the atlas, and serves to retain the odontoid process in firm connection with its anterior arch. This ligament is flattened from before backward, broader and thicker in the middle than at either extremity, and firmly attached on each side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus is derived from its upper, and another from its lower, border; the former passing upward, to be inserted into the anterior sur-

---

¹ It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the spine are regulated; so that the connections between the atlas and axis ought always to be studied together with those between the latter bones and the skull.

---

Fig. 199.—Occipital bone and first three cervical vertebrae with ligaments, from in front. (Spaltehola.)
ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. Since the space between the anterior arch of the atlas and the transverse ligament is smaller at the lower part than the upper (because the transverse ligament embraces tightly the narrow neck of the odontoid process), this process is retained in firm connection with the atlas after all the other ligaments have been divided.

The Capsular Ligaments (capsulae articulares) (Figs. 199, 200, and 202) are two thin and loose capsules, connecting the lateral masses of the atlas with the superior articular surfaces of the axis, the fibres being strengthened at the posterior and inner part of each articulation by an accessory ligament, which is attached below to the body of the axis near the base of the odontoid process.

Synovial Membranes (Fig. 201).—There are four synovial membranes in this articulation: one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, the atlanto-odontoid joint; and one between the posterior surface of the odontoid process and the transverse ligament, the syndesmo-odontoid joint. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

Actions.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments. The principal muscles by which this action is produced are the Sterno-mastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Tracheo-mastoid, Rectus capitis posticus major, and Inferior oblique of the other side.

ARTICULATIONS OF THE SPINE WITH THE CRANIUM.

The ligaments connecting the spine with the cranium may be divided into two sets—those connecting the occipital bone with the atlas, and those connecting the occipital bone with the axis.

III. Articulation of the Atlas with the Occipital Bone (Articulatio Atlantooccipitalis).

This articulation is a double condyloid joint. Its ligaments are the

Anterior Occipito-atlantal. Posterior Occipito-atlantal.

Two Capsular.

The Anterior Occipito-atlantal Ligament or Membrane (membrana atlantooccipitalis anterior, anterior occipito-atloidal ligament) (Figs. 199 and 203) is a broad membranous layer, composed of densely woven fibres, which passes between the anterior margin of the foramen magnum above, and the whole length of the upper border of the anterior arch of the atlas below. Laterally, it is continuous with the capsular ligaments. In the middle line in front it is strengthened by a strong, narrow, rounded cord, which is attached, above, to the basilar process of the occiput, and, below, to the tubercle on the anterior arch of the atlas, and which is a continuation of the anterior common ligament. This ligament is in relation, in front, with the Recti antici minores; behind, with the odontoid ligaments.

The Posterior Occipito-atlantal Ligament or Membrane (membrana atlantooccipitalis posterior, posterior occipito-atloidal ligament) (Figs. 200 and 203) is a very broad but thin membranous lamina intimately blended with the dura mater. It is connected, above, to the posterior margin of the foramen magnum; below, to the upper border
of the posterior arch of the atlas. This ligament is incomplete at each side, and forms, with the superior intervertebral notch, an opening for the passage of the vertebral artery and suboccipital nerve. The fibrous band which arches over the artery and nerve sometimes becomes ossified. The ligaments are in relation, behind, with the Recti postici minores and Obliqui superiores; in front, with the dura mater of the spinal canal, to which they are intimately adherent.

The Capsular Ligaments (capsulae articulares) (Fig. 202) surround the condyles of the occipital bone, and connect them with the articular processes of the atlas; they consist of thin and loose capsules, which enclose the synovial membranes of the articulations.

Synovial Membranes.—There are two synovial membranes in this articulation, one lining the inner surface of each of the capsular ligaments. These occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

Actions.—The movements permitted in this joint are flexion and extension, which give rise to the ordinary forward and backward nodding of the head. Slight lateral motion to one or the other side may also take place. When either of these actions is carried beyond a slight extent, the whole of the cervical portion of the spine assists in its production. Flexion is mainly produced by the action of the Rectus capitis anticus major et minor and the Sterno-mastoid muscles; extension by the
Rectus capitis posticus major et minor, the Superior oblique, the Complexus, Splenius, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius, Splenius, Complexus, and the Sterno-mastoid of the same side, all acting together. According to Cruveilhier, there is a slight motion of rotation in this joint.

IV. Articulation of the Axis with the Occipital Bone.

The ligaments of this articulation are the Occipito-axial. Three Odontoid.

To expose these ligaments the spinal canal should be laid open by removing the posterior arch of the atlas, the lamina and spinal process of the axis, and the portion of the occipital bone behind the foramen magnum, as seen in Fig. 192.

The Posterior Occipito-axial Ligament (posterior occipito-axoid ligament, membrana tectoria, apparatus ligamentosus colli) (Figs. 202 and 203) is situated within the spinal canal. It is a broad, strong band, which covers the odontoid process and its ligaments, and appears to be a prolongation upward of or a membrane due to fusion with the posterior common ligament of the spine. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it becomes blended with the dura mater of the skull.

Relations.—By its anterior surface with the transverse ligament; by its posterior surface with the posterior common ligament.

The Lateral Odontoid or Check Ligaments (ligamenta alaria) (Figs. 202 and 203) are strong, rounded, fibrous cords, which arise one on either side of the upper part of the odontoid process, and, passing obliquely upward and outward, are inserted into the rough depressions on the inner side of the condyles of the
occipital bone. In the triangular interval left between these ligaments another strong fibrous cord, ligamentum suspensorium, or middle odontoid ligament (ligamentum apicis dentis), may be seen, which passes almost perpendicularly from the apex of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior occipito-atlantal ligament and upper fasciculus of the transverse ligament of the atlas.

Actions.—The odontoid ligaments serve to limit the extent to which rotation of the cranium may be carried; hence, they have received the name of check ligaments.

In addition to these ligaments, which connect the atlas and axis to the skull, the ligamentum nuchae must be regarded as one of the ligaments by which the spine is connected with the cranium. It is described on page 273.

Surgical Anatomy.—The ligaments which unite the component parts of the vertebrae together are so strong, and these bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, unless accompanied by fracture, seldom occurs, except in the upper part of the neck. Dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common; it is the mode in which death is produced in many cases of execution by hanging. Ocicpito-atlial dislocation is certainly fatal. Recoveries are on record after atl-axoid dislocation. Immediate death occurs if the transverse ligament is torn or the odontoid process is broken. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.
V. Articulation of the Lower Jaw, or the Temporo-mandibular Articulation (Articulatio Mandibularis).

This is a ginglymo-arthrodial joint: the parts entering into its formation on each side are, above, the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis; and, below, the condyle of the lower jaw. The ligaments are the following:

- External Lateral
- Internal Lateral
- Stylo-mandibular
- Capsular
- Interarticular Fibro-cartilage

The **External Lateral Ligament** (ligamentum temporomandibulare) (Fig. 204) is a short, thin, and narrow fasciculus, attached, above, to the outer surface of the zygoma and to the tubercle on its lower border; below, to the outer surface and posterior border of the neck of the lower jaw. It is broader above than below; its fibres are placed parallel with one another, and directed obliquely downward and backward. Externally, it is covered by the parotid gland and by the integument. Internally it is in relation with the capsular ligament, of which it is an accessory band, and from which it is not separable.

The **Internal Lateral Ligament** (ligamentum sphenomandibulare) (Fig. 205) is a flat, thin band which is attached above to the spinous process of the sphenoid bone, and, becoming broader as it descends, is inserted into the margin of the mandibular or dental foramen and the portion of bone, the lingula, which overhangs the foramen in front. Its outer surface is in relation, above, with the External pterygoid muscle; lower down it is separated from the neck of the condyle by the internal maxillary artery; and still more inferiorly, the inferior dental vessels and nerve separate it from the ramus of the jaw. The inner surface is in relation with the Internal pterygoid. It is really the fibrous covering of a part of Meckel's cartilage.
The **Stylo-mandibular** or **Stylo-maxillary Ligament** (ligamentum stylomandibulare) (Fig. 205) is a specialized band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the lower jaw, between the Masseter and Internal pterygoid muscles. This ligament separates the parotid from the submaxillary gland, and has attached to its inner side part of the fibres of origin of the Styloglossus muscle. Although usually classed among the ligaments of the jaw, it can be considered only as an accessory to the articulation.

The **Capsular Ligament** (capsula articularis) (Figs. 204 and 205) forms a thin and loose capsule, passing from the circumference of the glenoid cavity and the articular surface immediately in front to the upper margin of the articular disk, and from the lower margin of the articular disk to the neck of the condyle of the lower jaw. It consists of very thin fibres, and is complete. It forms two joint cavities, distinct from each other, and separated by the articular disk. So thin is it that it is hardly to be considered as a distinct ligament; it is thickest at the back part, and thinnest on the inner side of the articulation.¹

The **Interarticular Fibro-cartilage** or **Meniscus** (discus articularis) (Fig. 206) is a thin plate of an oval form, placed horizontally between the condyle of the jaw and the glenoid cavity. Its upper surface is concavo-convex from before backward, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, where it is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament, and in front to the tendon of the External pterygoid muscle. It is thicker at its circumference, especially behind, than at its centre. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane from the capsular ligament.

**Synovial Membranes** (Fig. 206).—The synovial membranes, **two** in number, are placed, one above, and the other below, the fibro-cartilage. The **upper one**, the larger and looser of the two, is continued from the margin of the cartilage covering

¹ Sir G. Humphry describes the internal portion of the capsular ligament separately as the short internal lateral ligament; and it certainly seems as deserving of a separate description as is the external lateral ligament.
the glenoid cavity and eminentia articularis on to the upper surface of the fibro-cartilage. The lower one passes from the under surface of the fibro-cartilage to the neck of the condyle of the jaw, being prolonged downward a little farther behind than in front. The interarticular cartilage is sometimes perforated in its centre; the two synovial sacs then communicate with each other.

The nerves of this joint are derived from the auriculo-temporal and masseteric branches of the inferior maxillary. The arteries are derived from the temporal branch of the external carotid.

**Actions.**—The movements possible in this articulation are very extensive. Thus, the jaw may be depressed or elevated, or it may be carried forward or backward. It must be borne in mind that there are two distinct joints in this articulation—that is to say, one between the condyle of the jaw and the interarticular fibro-cartilage, and another between the fibro-cartilage and the glenoid fossa; when the jaw is depressed, as in opening the mouth, the movements which take place in these two joints are not the same. In the lower compartment, that between the condyle and the fibro-cartilage, the movement is of a ginglymoid or hinge-like character, the condyle rotating on a transverse axis on the fibro-cartilage; while in the upper compartment the movement is of a gliding character, the fibro-cartilage, together with the condyle, gliding forward on to the eminentia articularis. These two movements take place simultaneously—the condyle and fibro-cartilage move forward on the eminence, and at the same time the condyle revolves on the fibro-cartilage. In the opposite movement of shutting the mouth the reverse action takes place; the fibro-cartilage glides back, carrying the condyle with it, and this at the same time revolves back to its former position. When the jaw is carried horizontally forward, as in protruding the lower incisors in front of the upper, the movement takes place principally in the upper compartment of the joint: the fibro-cartilage, carrying with it the condyle, glides forward on the glenoid fossa. This is because this movement is mainly effected by the External pterygoid muscles, which are inserted into both condyle and interarticular fibro-cartilage. The grinding or chewing movement is produced by the alternate movement of one condyle, with its fibro-cartilage, forward and backward, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on its own axis on the fibro-cartilage in the lower compartment. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

The lower jaw is depressed by its own weight, assisted by the Platysma, the Digastric, the Mylo-hyoid, and the Genio-hyoid muscles. It is elevated by the anterior part of the Temporal, Masseter, and Internal pterygoid. It is drawn forward by the simultaneous action of the External pterygoid and the superficial fibres of the Masseter; and it is drawn backward by the deep fibres of the Masseter and the posterior fibres of the Temporal muscle. The grinding movement is caused by the alternate action of the two External pterygoids.

**Surface Form.**—The temporo-mandibular articulation is quite superficial, situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter muscle. Its exact position can be at once ascertained by feeling for the condyle of the jaw, the working of which can be distinctly felt in the movements of the lower jaw in opening and shutting the mouth. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the eminentia articularis, and a depression is felt in the situation of the joint.

**Surgical Anatomy.**—Genuine dislocation of the lower jaw is always forward. Croker, King, and Theim, however, have reported posterior displacement. Dislocation is caused by violence or muscular action. When the mouth is open, the condyle is situated on the eminentia articularis, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forward into the zygomatic fossa. The displacement may be unilateral or bilateral, according as one or both of the condyles are displaced. The latter of
the two is the more common. The interarticular fibro-cartilage adheres to the condyle till it passes over the eminentia articularis, but at this point remains behind.

Sir Astley Cooper described a condition which he termed "subluxation." It occurs principally in delicate women, and is believed by some to be due to the relaxation of the ligaments, permitting too free movement of the bone. Others believe it is due to displacement of the interarticular fibro-cartilage. Still others attribute the symptoms to gouty or rheumatic changes in the joint. In close relation to the condyle of the jaw is the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to the ear, or on the other hand inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. In children, arthritis of this joint may follow the exanthema, and in adults it occurs as the result of some constitutional conditions, as rheumatism or gout. The temporo-mandibular joint is also occasionally the seat of osteo-arthritis, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the lower jaw, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

VI. Articulations of the Ribs with the Vertebrae or the Costo-vertebral Articulations (Articulationes Costovertebræ). The articulations of the ribs with the vertebral column may be divided into two sets: 1. Those which connect the heads of the ribs with the bodies of the vertebrae; costo-central. 2. Those which connect the necks and tubercles of the ribs with the transverse processes; costo-transverse.

1. Articulations between the Heads of the Ribs and the Bodies of the Vertebrae or the Costo-central Articulations (Articulationes Capitulorum) (Figs. 207 and 208).

These constitute a series of arthrodial joints, formed by the articulation of the heads of the ribs with the cavities on the contiguous margins of the bodies of the

Fig. 207.—Spinal column with ligament, from in front. (Spalteholz.)
dorsal vertebrae and the intervertebral substance between them, except in the case of the first, tenth, eleventh, and twelfth ribs, where the cavity is formed by a single vertebra. The bones are connected by the following ligaments:

Anterior Costo-vertebral or Stellate. 
Capsular. 
Interarticular.

The Anterior Costo-vertebral or Stellate Ligament (ligamentum capituli costae radiatum) (Figs. 207 and 210) connects the anterior part of the head of each rib with the sides of the bodies of two vertebrae and the intervertebral disk between them. It consists of three flat bundles of ligamentous fibres, which are attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres pass upward to be connected with the body of the vertebra above; the inferior one descends to the body of the vertebra below; and the middle one, the smallest and least distinct, passes horizontally inward, to be attached to the intervertebral substance.

Relations.—In front, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; behind, with the interarticular ligament and synovial membranes.

On the first rib, which articulates with a single vertebra, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body of the vertebra with which the rib articulates. In the tenth, eleventh, and twelfth ribs also, which likewise articulate with a single vertebra, the division does not exist; but the fibres of the ligament in each case radiate and are connected with the vertebra above, as well as that with which the ribs articulate.

The Capsular Ligament (capsula articularis) is a thin and loose ligamentous bag, which surrounds the joint between the head of the rib and the articular cavity formed by the intervertebral disk and the adjacent vertebra. It is very thin, firmly connected with the anterior ligament, and most distinct at the upper and lower parts of the articulation. Behind, some of its fibres pass through the intervertebral foramen to the back of the intervertebral disk. This is the analogue of the ligamentum conjugale of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disk.

The Interarticular Ligament (ligamentum capituli costae interarticulare) (Figs. 208 and 209) is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downward, attached by one extremity to the sharp crest which separates the two articular facets on the head of the rib, and by the other to the intervertebral disk. It divides the joint into two cavities, which have no communication with each other. In the first, tenth, eleventh, and
twelfth ribs the interarticular ligament does not exist; consequently there is but one synovial membrane.

**Synovial Membranes** (Figs. 208 and 209).—There are two synovial membranes in each of the articulations in which there is an interarticular ligament, one on each side of this structure.

2. Articulations of the Necks and Tubercles of the Ribs with the Transverse Processes or the **Costo-transverse Articulations** (Articulationes Costotransversarle) (Fig. 209).

The articular portion of the tubercle of the rib and adjacent transverse process form an arthrodial joint.

In the eleventh and twelfth ribs this articulation is wanting.

The ligaments connecting these parts are the

- **Anterior Superior** Costo-transverse
- **Middle** Costo-transverse (Interosseous)
- **Capsular**

**The Anterior Superior or Long** Costa-transverse Ligament (ligamentum costo-transversarium anterius) (Figs. 207, 208, 209, and 210) consists of two sets of fibres: the one (anterior) is attached below to the sharp crest on the upper border

Fig. 209.—Costo-transverse articulation. Seen from above.

of the neck of each rib, and passes obliquely upward and outward to the lower border of the transverse process immediately above; the other (posterior) is attached below to the neck of the rib, and passes upward and inward to the base of the transverse process and outer border of the lower articular process of the vertebra above. This ligament is in relation, in front, with the intercostal vessels and nerves; behind, with the Longissimus dorsi muscle. Its internal border is thickened and free, and bounds an aperture through which pass the posterior branches of the intercostal vessels and nerves. Its external border is continuous with a thin aponeurosis which covers the External intercostal muscle.

The first rib has no anterior costo-transverse ligament. In the twelfth rib the ligament is absent or is a mere vestige.
The Middle Costo-transverse or Interosseous Ligament (ligamentum colli costae) (Fig. 209) consists of short but strong fibres which pass between the rough surface on the posterior part of the neck of each rib and the anterior surface of the adjacent transverse process. In order fully to expose this ligament, a horizontal section should be made across the transverse process and corresponding part of the rib; or the rib may be forcibly separated from the transverse process and the fibres of the ligament put on the stretch.

In the eleventh and twelfth ribs this ligament is quite rudimentary or wanting. The Posterior Costo-transverse Ligament (ligamentum costotransversarium posterius) (Fig. 209) is a short but thick and strong fasciculus which passes obliquely from the summit of the transverse process to the rough non-articular portion of the tubercle of the rib. This ligament is shorter and more oblique in the upper than in the lower ribs. Those corresponding to the superior ribs ascend, while those of the inferior ribs descend slightly.

In the eleventh and twelfth ribs this ligament is wanting.

The Capsular Ligament (capsula articularis) is a thin, membranous sac attached to the circumference of the articular surfaces, and enclosing a small synovial membrane.

In the eleventh and twelfth ribs this ligament is absent.

Actions.—The heads of the ribs are so closely connected to the bodies of the vertebrae by the stellate and interarticular ligaments, and the necks and tubercles of the ribs to the transverse processes, that only a slight sliding movement of the articular surfaces on each other can take place in these articulations. The result of this gliding movement with respect to the six upper ribs consists in an elevation of the front and middle portion of the rib, the hinder part being prevented from performing any upward movement by its close connection with the spine. In this gliding movement the rib rotates on an axis corresponding with a line drawn through the two articulations, costo-central and costo-transverse, which the rib forms with the spine. With respect to the seventh, eighth, ninth, and tenth ribs, each one, besides rotating in a similar manner to the upper six, also rotates on an axis corresponding with a line drawn from the head of the rib to the sternum. By the first movement—that of rotation of the rib on an axis corresponding with a line drawn through the two articulations which this bone forms with the spine—an elevation of the anterior part of the rib takes place, and a consequent enlargement of the antero-posterior diameter of the chest. None of the ribs lie in
a truly horizontal plane; they are all directed more or less obliquely, so that their anterior extremities lie on a lower level than their posterior, and this obliquity increases from the first to the seventh, and then again decreases. If we examine any one rib—say, that in which there is the greatest obliquity—we shall see that it is obvious that as its sternal extremity is carried upward, it must also be thrown forward; so that the rib may be regarded as a radius moving on the vertebral joint as a centre, and causing the sternal attachment to describe an arc of a circle in the vertical plane of the body. Since all the ribs are oblique and connected in front to the sternum by the elastic costo-cartilages, they must have a tendency to thrust the sternum forward, and so increase the antero-posterior diameter of the chest. By the second movement—that of the rotation of the rib on an axis corresponding with a line drawn from the head of the rib to the sternum—an elevation of the middle portion of the rib takes place, and consequently an increase in the transverse diameter of the chest. For the ribs not only slant downward and forward from their vertebral attachment, but they are also oblique in relation to their transverse plane—that is to say, their middle is on a lower level than either their vertebral or sternal extremities. It results from this that when the ribs are raised, the centre portion is thrust outward, somewhat after the fashion in which the handle of a bucket is thrust away from the side when raised to a horizontal position, and the lateral diameter of the chest is increased (see Fig. 211). The mobility of the different ribs varies very much. The first rib is more fixed than the others, on account of the weight of the upper extremity and the strain of the ribs beneath; but on the freshly dissected thorax it moves as freely as the others. From the same causes the movement of the second rib is also not very extensive. In the other ribs this mobility increases successively down to the last two, which are very movable. The ribs are generally more movable in the female than in the male.

VII. Articulation of the Cartilages of the Ribs with the Sternum, etc., or the Costo-sternal Articulations (Articulationes Sternocostales) (Fig. 212).

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is almost always
directly united with the sternum, and which must therefore be regarded as a synarthrodial articulation. The ligaments connecting them are the

Anterior Chondro-sternal. Capsular.
Posterior Chondro-sternal. Interarticular Chondro-sternal.
Chondro-xiphoid.

The **Anterior Chondro-sternal** or **Sterno-costal Ligament** (*ligamentum sternocostale radiatum*) (Fig. 212) is a broad and thin membranous band that radiates from the front of the inner extremity of the cartilages of the true ribs to the anterior surface of the sternum. It is composed of fasciiculi which pass in different directions. The **superior fasciculi** ascend obliquely, the **inferior fasciculi** pass obliquely downward, and the **middle fasciculi** pass horizontally. The superficial fibres of this ligament are the longest: they intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane which covers the surface of the sternum (*membrana sterni*). This is more distinct at the lower than at the upper part. According to the modern nomenclature, this ligament and the posterior chondro-sternal ligament are called **ligamenta sternocostalia radiata**. The two chondro-sternal ligaments form a sheath for the sternum anteriorly and posteriorly, the **membrana sterni**.

The **Posterior Chondro-sternal** or **Sterno-costal Ligament** (*ligamentum sternocostale radiatum*), less thick and distinct than the anterior, is composed of fibres which radiate from the posterior surface of the sternal end of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The **Capsular Ligament** (*capsula articularis*) surrounds the joint formed between the cartilage of a true rib and the sternum. It is very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower part of the articulation by a few fibres which pass from the cartilage to the side of the sternum. These ligaments protect the synovial membranes.

The **Interarticular Chondro-sternal** or **Sterno-costal Ligament** (*ligamentum sternocostale interarticulare*) (Fig. 212).—This is found between the second costal cartilage and the sternum. The cartilage of the second rib is connected with the sternum by means of an interarticular ligament attached by one extremity to the cartilage of the second rib, and by the other extremity to the cartilage which unites the first and second pieces of the sternum. This articulation is provided with two synovial membranes. The cartilage of the third rib is also connected with the sternum by means of an interarticular ligament which is attached by one extremity to the cartilage of the third rib, and by the other extremity to the point of junction of the second and third pieces of the sternum. This articulation may be provided with two synovial membranes. In the other joints interarticular ligaments may exist, but they rarely completely divide the joint into two cavities.

The **Anterior Chondro-xiphoid** or **Costo-xiphoid Ligament** (*ligamentum costo-xiphoidea*) (Fig. 212).—This is a band of ligamentous fibres which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform appendix. It varies in length and breadth in different subjects. A similar band of fibres on the internal or posterior surface, though less thick and distinct, may be demonstrated. It is spoken of as the **posterior chondro-xiphoid** or **costo-xiphoid ligament**.

**Synovial Membranes** (Fig. 212).—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the sternum. There are two synovial membranes, both in the articulation of the second and third costal cartilages to the sternum. There is generally one synovial membrane in each of the joints between the fourth, fifth, sixth, and seventh
costal cartilages to the sternum; but it is sometimes absent in the sixth and seventh chondro-sternal joints. Thus there are usually eight synovial cavities on each side in the articulations between the costal cartilages of the true ribs and the sternum. After middle life the articular surfaces lose their polish, become

roughened, and the synovial membranes appear to be wanting. In old age the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

**Actions.**—The movements which are permitted in the chondro-sternal articulations are limited to *elevation* and *depression*, and these only to a slight extent.

**Articulations of the Cartilages of the Ribs with Each Other or the Intercostal Articulations** (*articulationes interchondrales*) (Fig. 212).—The con-

Fig. 212.—Sternum and ribs with ligaments, from in front. In the left half of the figure the most anterior layer has been removed and the joint slits have been opened; the parts are separated somewhat from one another on the left side. (Spalteholz.)
tiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth, oblong-shaped facets. Each articulation is enclosed in a thin capsular ligament lined by synovial membrane, and strengthened externally and internally by ligamentous fibres, external and internal interchondral ligaments (ligamenta intercostalia externa et interna), which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates, by its lower border, with the adjoining cartilage by a small oval facet; more frequently they are connected together by a few ligamentous fibres. Occasionally the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages or the Costa-chondral Articulations (Fig. 212).—The outer extremity of each costal cartilage is received into a depression in the sternal ends of the ribs, and the two are held together by the periosteeum. There is no real joint. Occasionally a synovial membrane exists between the first rib and the corresponding cartilage.

VIII. Articulations of the Sternum (Fig. 212).

The first piece of the sternum is united to the second either by an amphiarthrodial joint—a single piece of true fibro-cartilage uniting the segments—or by a diarthrodial joint, in which each bone is clothed with a distinct lamina of cartilage, adherent on one side, free and lined with synovial membrane on the other. In the latter case the cartilage covering the gladiolus is continued without interruption on to the cartilages of the second ribs. Mr. Rivington has found the diarthrodial form of joint in about one-third of the specimens examined by him; Mr. Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Mr. Rivington’s opinion, from the amphiarthrodial form by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. Professor Cunningham1 says: “It is not usual to find the manubri-gladiolar joint obliterated by the ossification of the two bony segments. Even in advanced life it remains open, and the joint partakes of the nature of an amphiarthrosis, although a joint cavity is not found under any circumstances in the plate of fibro-cartilage which intervenes between the manubrium and the gladiolus.” The two segments are further connected by an

Anterior Intersternal Ligament. Posterior Intersternal Ligament.

The Anterior Intersternal Ligament consists of a layer of fibres, having a longitudinal direction; it blends with the fibres of the anterior chondro-sternal ligaments on both sides (membranis sternii), and with the tendinous fibres of origin of the Pectoralis major muscle. This ligament is rough, irregular, and much thicker below than above.

The Posterior Intersternal Ligament is disposed in a somewhat similar manner on the posterior surface of the articulation.

IX. Articulation of the Vertebral Column with the Pelvis.

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which connect the segments of the spine with each other—viz.: 1. The continuation downward of the anterior and posterior common ligaments. 2. The intervertebral substance connecting the flattened oval surfaces of the two bones.

1 Text-book of Anatomy, p. 264.
and forming an amphiarthrodial joint. 3. Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the sacral canal. 4. Capsular ligaments connecting the articulating processes and forming a double arthrodia. 5. Inter- and supraspinous ligaments.

The two proper ligaments connecting the pelvis with the spine are the lumbo-sacral and ilio-lumbar.

The **Lumbo-sacral Ligament** (Fig. 213) is a short, thick, triangular fasciculus, which is connected above to the lower and front part of the transverse process of the last lumbar vertebra, passes obliquely outward, and is attached below to the lateral surface of the base of the sacrum. It is closely blended with the anterior sacro-iliac ligament and with the ilio-lumbar ligament, and is to be regarded as a portion of the ilio-lumbar ligament. This ligament is in relation, in front, with the Psoas muscle. The internal border of the lumbo-sacral ligament margins the foramen of the last lumbar nerve.

The **Ilio-lumbar Ligament** (*ligamentum iliolumbale*) (Fig. 213) passes horizontally outward from the apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacro-iliac articulation. It is of a triangular form, thick and narrow internally, broad and thinner externally. It is in relation, in front, with the Psoas muscle; behind, with the muscles occupying the vertebral groove; above, with the Quadratus lumborum. It blends in places with the lumbo-sacral ligament, and its crescentic inner margin marks the limit of the foramen for the fourth lumbar nerve. These ligaments are thick prolongations from the anterior layer of the lumbar fascia.
X. Articulations of the Pelvis.

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those connecting the sacrum and coccyx. 4. Those between the two pubic bones.

1. Articulation of the Sacrum and Ilium (Articulatio Sacroiliaca.)

The sacro-iliac articulation is an amphiarthrodial joint, formed between the lateral surfaces of the sacrum and ilium. The anterior or auricular portion of each articular surface is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. These are in close contact with each other, and to a certain extent united together by irregular patches of softer fibro-cartilage, and at their upper and posterior part by fine fibres of interosseous fibrous tissue. Throughout a considerable part of their extent, especially in advanced life, they are not connected together, but are separated by a space containing a synovial-like fluid, and hence the joint presents the characters of a diarthrosis.

The ligaments connecting these surfaces are the

The Anterior Sacro-iliac Ligaments (ligamenta sacroiliaca anteriors) (Fig. 213) consists of numerous thin bands which connect the anterior surfaces of the sacrum and ilium.

The Posterior Sacro-iliac Ligament (ligamentum sacroiliacum posterius) (Fig. 214) is a strong interosseous ligament, situated in a deep depression between the sacrum and ilium behind, and forming the chief bond of connection between those bones. It consists of numerous strong fasciculi which pass between the bones in various directions. Three of these are of large size: the two superior fasciculi constitute the short sacro-iliac ligament (ligamentum sacroiliacum posterius breve). They are nearly horizontal in direction, arise from the first and second transverse tubercles on the posterior surface of the sacrum, and are inserted into the rough, uneven surface at the posterior part of the inner surface of the ilium. The third fasciculus, oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; it is sometimes called the long or oblique sacro-iliac ligament (ligamentum sacroiliacum posterius longum).

The Interosseous Ligaments (ligamenta sacroiliaca interossea) are completely covered by the posterior sacro-iliac ligament, and are not visible when the joint is unopened. The fibres are short and run obliquely and completely fill the hollow which exists posterior to the joint.

The position of the sacro-iliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

2. Ligaments passing between the Sacrum and Ischium (Fig. 214).

The Great Sacro-sciatic (Posterior).
The Lesser Sacro-sciatic (Anterior).

The Great or Posterior Sacro-sciatic Ligament (ligamentum sacrotuberosum) (Figs. 214 and 215) is situated at the lower and back part of the pelvis. It is flat, and triangular in form; narrower in the middle than at the extremities; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth trans-
verse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downward, outward, and forward, it becomes narrow and thick, and at its insertion into the inner margin of the tuberosity of the ischium it increases in breadth, and is prolonged forward along the inner margin of the ramius, forming what is known as the falciform process of the great sacro-sciatic ligament or the falciform ligament (processus falciformis). The free concave edge of this prolongation has attached to it the obturator fascia, with which it forms a kind of groove, protecting the internal pudic vessels and nerve. One of its surfaces is turned toward the perineum, the other toward the Obturator internus muscle.

The posterior surface of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus muscle. Its anterior surface is united to the lesser sacro-sciatic ligament. Its external border forms, above, the posterior boundary of the great sacro-sciatic foramen, and, below, the posterior boundary of the lesser sacro-sciatic foramen. Its lower border forms part of the boundary of the perineum. It is pierced by the coccygeal branch of the sciatic artery and the coccygeal nerve.

The Lesser or Anterior Sacro-sciatic Ligament (ligamentum sacrospinorum) (Figs. 214 and 215), much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, anterior to the attachment of the great sacro-sciatic ligament, with which its fibres are intermingled.

It is in relation, anteriorly, with the Coccygeus muscle; posteriorly, it is covered by the great sacro-sciatic ligament and crossed by the internal pudic vessels and nerve. Its superior border forms the lower boundary of the great sacro-sciatic foramen; its inferior border, part of the lesser sacro-sciatic foramen.
These two ligaments convert the sacro-sciatic notches into foramina. The **superior** or **great sacro-sciatic foramen** (*foramen ischiadicum majus*) (Figs. 214 and 215) is bounded, in front and above, by the posterior border of the os innominatum; behind, by the great sacro-sciatic ligament; and below, by the lesser sacro-sciatic ligament. It is partially filled up, in the recent state, by the Piriformis muscle, which passes through it. Above this muscle the gluteal vessels and superior gluteal nerve emerge from the pelvis, and, below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, the inferior gluteal nerve, and the nerves to the obturator internus and quadratus femoris. The **inferior** or **lesser sacro-sciatic foramen** (*foramen ischiadicum minus*) (Figs. 214 and 215) is bounded, in front, by the

tuber ischii; above, by the spine and lesser sacro-sciatic ligament; behind, by the greater sacro-sciatic ligament. It transmits the tendon of the Obturator internus muscle, its nerve, and the internal pudic vessels and nerve.

3. **Articulation of the Sacrum and Coccyx (Symphysis Sacrococcygea).**

This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum and the base of the coccyx. It is analogous to the joints between the bodies of the vertebrae. The ligaments are the

- Anterior Sacro-coccygeal.
- Posterior Sacro-coccygeal.
- Interposed Fibro-cartilage.

The **Anterior Sacro-coccygeal Ligament** (*ligamentum sacrococcygeum anterius*) consists of a few irregular fibres which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum. It is a continuation of the anterior common ligament.

The **Posterior Sacro-coccygeal Ligament** (*ligamentum sacrococcygeum posterius*) (Fig. 216) is divided into two portions, the deep and the superficial. The deep
portion of the posterior sacro-coccygeal ligament (ligamentum sacroccocygeum posterius profundum), which is a continuation of the posterior common ligament, is a flat band of a pearly tint, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal. Its superficial fibres are much longer than the more deeply seated. This ligament is in relation, behind, with the Gluteus maximus.

The superficial portion of the posterior sacro-coccygeal ligament (ligamentum sacroccocygeum posterius superficiale) is composed of longitudinal fibrous bands which extend from the lower portion of the middle sacral ridge to the posterior surface of the coccyx and closes partly the hiatus sacralis; and of fibrous bands which extend from the sacral cornua to the coccygeal cornua. A portion of this ligament corresponds to the ligamenta subflava and the balance to the capsular ligament.

A Lateral Sacro-coccygeal or Intertransverse Ligament (ligamentum sacroccocygeum laterale) (Fig. 216) connects the transverse process of the coccyx to the lower lateral angle of the sacrum on each side.

A Fibro-cartilage is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from that interposed between the bodies of the vertebrae in being thinner, and its central part firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally, a synovial membrane is found and the coccyx is freely movable. This is especially the case during pregnancy.

The different segments of the coccyx are connected together by an extension downward of the anterior and posterior sacro-coccygeal ligaments, a thin annular disk of fibro-cartilage being interposed between each of the bones. In the adult male all the pieces become ossified, but in the female this does not commonly occur until a later period of life. The separate segments of the coccyx are first united, and at a more advanced age the joint between the sacrum and coccyx is obliterated.

Actions.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are forward and backward, and are very limited. Their extent increases during pregnancy.
4. Articulation of the Ossa Pubis (Symphysis Ossium Pubis) (Figs. 213, 217).

The articulation between the pubic bones is an amphiarthrodial joint, formed by the junction of the two oval articular surfaces of the ossa pubis. The ligaments of this articulation are the

Anterior Public.  Superior Public.
Posterior Public.  Inferior Public.
Interpubic Disk.

The **Anterior Pubic Ligament** (ligamentum pubicum anterius) (Fig. 213) consists of several superimposed layers which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeurosis of the External oblique and the tendon of the Rectus muscles. The deep fibres pass transversely across the symphysis, and are blended with the fibro-cartilage.

The **Posterior Pubic Ligament** (ligamentum pubicum posterius) consists of a few thin, scattered fibres which unite the two pubic bones posteriorly.

The **Superior Pubic Ligament** (ligamentum pubicum superiorius) (Fig. 213) is a band of fibres which connects together the two pubic bones superiorly.

The **Inferior Pubic or Subpubic Ligament** (ligamentum arcuatum pubis) (Fig. 213) is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below and forming the upper boundary of the pubic arch. Above, it is blended with the interarticular fibro-cartilage; laterally it is united with the descending rami of the pubis. Its fibres are closely connected and have an arched direction. Its lower margin is separated from the triangular ligament of the perineum by a gap, through which runs the dorsal vein of the penis.

The **Interpubic Disk** (lamina fibrocartilaginea interpubica) (Fig. 217) consists of a disk of cartilage and fibro-cartilage connecting the surfaces of the pubic bones in front. Each of the two surfaces is covered by a thin layer of hyaline cartilage which is firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate stratum of fibrous tissue and fibro-cartilage which varies in thickness in different subjects. It often contains a cavity (cavum articularare) in its centre, probably formed by the softening and absorption of the fibro-cartilage, since it rarely appears before the tenth year of life, and is not lined by synovial membrane. It is larger in the female than in the male, but it is very questionable whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint, but it occasionally reaches to the front, and may extend the entire length of the cartilage. This cavity may be easily demonstrated by making a vertical section of the symphysis pubis near its posterior surface (Fig. 217).

The **Obturator Ligament** is more properly regarded as analogous to the muscular fasciae, with which it will be described.
ARTICULATIONS OF THE UPPER EXTREMITY.

The articulations of the upper extremity may be arranged in the following groups:

I. Sterno-clavicular Articulation.  
II. Acromio-clavicular Articulation.  
III. Ligaments of the Scapula.  
IV. Shoulder-joint.  
V. Elbow-joint.  
VI. Radio-ulnar Articulations.  
VII. Wrist-joint.  
VIII. Articulations of the Carpal Bones.  
IX. Carpo-metacarpal Articulations.  
X. Metacarpo-phalangeal Articulations.  
XI. Articulations of the Phalanges.

I. Sterno-clavicular Articulation (Articulatio Sternoclavicularis) (Fig. 218).

The sterno-clavicular is regarded by most anatomists as an arthrodial joint, but Cruveilhier considers it to be an articulation by reciprocal reception. Probably the former opinion is the correct one, the varied movement which the joint enjoys being due to the interposition of an interarticular fibro-cartilage between the joint surfaces. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the first piece of the sternum, and the cartilage of the first rib. The articular surface of the sternum is covered with cartilage. The articular surface of the clavicle is much larger than that of the sternum, and invested with a layer of cartilage which is considerably thicker than that on the latter bone. The ligaments of this joint are the

Capsular.  
Anterior Sterno-clavicular.  
Posterior Sterno-clavicular.  
Interclavicular.  
Costo-clavicular.  
Interarticular Fibro-cartilage.

The Capsular Ligament (capsula articularis) completely surrounds the articulation, consisting of fibres of varying degrees of thickness and strength. Those in front and behind are of considerable thickness, and form the anterior and posterior sterno-clavicular ligaments; but those above and below, especially in the latter situation, are thin and scanty, and partake more of the character of connective tissue than true fibrous tissue.

1 According to Bruch, the sternal end of the clavicle is covered by a tissue which is rather fibrous than cartilaginous in structure.
The **Anterior Sterno-clavicular Ligament** *(ligamentum sternoclavicularare)* (Fig. 218) is a part of the capsule. It is a broad band of fibres which covers the anterior surface of the articulation, being attached, above, to the upper and front part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, below, to the upper and front part of the first piece of the sternum. This ligament is covered, in front, by the sternal portion of the Sterno-cleido-mastoid and the integument; behind, it is in relation with the interarticular fibro-cartilage and the two synovial membranes.

The **Posterior Sterno-clavicular Ligament**, also a part of the capsule, is a band of fibres which covers the posterior surface of the articulation, being attached, above, to the upper and back part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, below, to the upper and back part of the first piece of the sternum. It is in relation, in front, with the interarticular fibro-cartilage and synovial membranes; behind, with the Sterno-hyoid and Sterno-thyroid muscles.

The **Interclavicular Ligament** *(ligamentum interclavicularare)* (Fig. 218) is a flattened band which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to the other, and is also attached to the upper margin of the sternum. It is in relation, in front, with the integument; behind, with the Sterno-thyroid muscles.

The **Costo-clavicular or Rhomboid Ligament** *(ligamentum costoclavicularare)* (Fig. 218) is short, flat, and strong; it is of a rhomboid form, attached, below, to the upper and inner part of the cartilage of the first rib: it ascends obliquely backward and outward, and is attached, above, to the rhomboid depression on the under surface of the clavicle. It is in relation, in front, with the tendon of origin of the Subclavius; behind, with the subclavian vein.

The **Interarticular Fibro-cartilage** *(discus articularis)* (Fig. 218) is a flat and nearly circular meniscus, interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, at its junction with the sternum; and by its circumference, to the anterior and posterior sterno-clavicular and the interclavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre or below. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

**Synovial Membrane.**—Of the two synovial membranes found in this articulation, one is reflected from the sternal end of the clavicle over the adjacent surface of the fibro-cartilage and cartilage of the first rib; the other is placed between the articular surface of the sternum and adjacent surface of the fibro-cartilage; the latter is the larger of the two.

**Actions.**—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upward, downward, backward, forward—as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk. “The movements attendant on elevation and depression of the shoulder take place between the clavicle and the interarticular fibro-cartilage, the bone rotating upon the ligament on an axis drawn from before backward through its own articular facet. When the shoulder is moved forward and backward, the clavicle, with the interarticular fibro-cartilage, rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, round an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded
of these two movements, the clavicle revolves upon the interarticular fibro-cartilage, and the latter, with the clavicle, rolls upon the sternum.\footnote{Humphry. On the Human Skeleton, p. 402.} Elevation of the clavicle is principally limited by the costo-clavicular ligament; depression by the interclavicular. The muscles which raise the clavicle, as in shrugging the shoulder, are the upper fibres of the Trapezius, the Levator anguli scapulae, the clavicular head of the Sterno-mastoid, assisted to a certain extent by the two Rhomboids, which pull the vertebral border of the Scapula backward and upward, and so raise the clavicle. The depression of the clavicle is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn backward by the Rhomboids and the middle and lower fibres of the Trapezius; and forward by the Serratus magnus and Pectoralis minor.

Surface Form.—The position of the sterno-clavicular joint may be easily ascertained by feeling the enlarged sternal end of the collar-bone just external to the long, cord-like, sternal origin of the Sterno-mastoid muscle. If this muscle is relaxed by bending the head forward, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint, which is subcutaneous. When the arm hangs by the side, the cavity of the joint is V-shaped. If the arm is raised, the bones become more closely approximated, and the cavity becomes a mere slit.

Surgical Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is because of the ligaments and because the force of a blow is generally transmitted along the long axis of the clavicle, that dislocation so rarely occurs, and that the bone is generally broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence was applied than upon the anatomical construction of the joint; it may be either forward, backward, or upward. A complete upward dislocation is also inward. A complete forward or backward dislocation is also inward and downward. The chief point worthy of note, as regards the construction of the joint, in regard to dislocations, is the fact that, owing to the shape of the articular surfaces being so little adapted to each other, and that the strength of the joint mainly depends upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place, and it may be necessary to incise the soft parts and wire the bone in place.

II. Acromio-clavicular Articulation or Scapulo-clavicular Articulation (Articulatio Acromioclavicularis) (Fig. 219).

The acromio-clavicular is an arthrodial joint formed between the outer extremity of the clavicle and the inner margin of the acromion process of the scapula. The ligaments which surround the joint form a capsule. The ligaments of this articulation are the

- Superior Acromio-clavicular
- Inferior Acromio-clavicular
- Interarticular Fibro-cartilage

The Superior Acromio-clavicular Ligament (ligamentum acromio-clavicular) (Figs. 219 and 220) is a portion of the joint capsule. It is a quadrilateral band which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres which interlace with the aponeurosis of the Trapezius and Deltoid muscles; below, it is in contact with the interarticular fibro-cartilage (when it exists) and the synovial membranes.

The Inferior Acromio-clavicular Ligament, somewhat thinner than the preceding, and like it a portion of the capsule, covers the under part of the articulation, and is attached to the adjoining surfaces of the two bones. It is in relation, above, with the synovial membranes, and in rare cases with the interarticular fibro-cartilage; below, with the tendon of the Supraspinatus. These two liga-
ments are continuous with each other in front and behind, and form a complete capsule round the joint.

The **Interarticular Fibro-cartilage** (*discus articularis*) is frequently absent in this articulation. When the meniscus exists it is generally incomplete and only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely it completely separates the joint into two cavities.

![Fig. 219.—The left shoulder-joint, scapulo-clavicular articulations, and proper ligaments of scapula.](image)

**The Synovial Membrane.**—There is usually only one synovial membrane in this articulation, but when a complete interarticular fibro-cartilage exists there are two synovial membranes.

The **Coraco-clavicular Ligament** (*ligamentum coraco-claviculare*) (Figs. 219 and 220) serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but as it forms a most efficient means in retaining the clavicle in contact with the acromial process, it is usually described with it. It consists of two fasciculi, called the **trapezoid** and **conoid ligaments**.

The **trapezoid ligament** (*ligamentum trapezoideum*), the anterior and external fasciculus, is broad, thin, and quadrilateral; it is placed obliquely between the coracoid process and the clavicle. It is attached, below, to the upper surface of the coracoid process; above, to the oblique line on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament, the two forming by their junction a projecting angle.

The **conoid ligament** (*ligamentum conoideum*), the posterior and internal fasciculus, is a dense band of fibres, conical in form, the base being directed upward, the summit downward. It is attached by its apex to a rough impression at the base of the coracoid process, internal to the preceding; above, by its expanded
base, to the conoid tubercle on the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are in relation, in front, with the Subclavius and Deltoid; behind, with the Trapezius. They serve to limit rotation of the scapula, the Trapezioid limiting rotation forward, and the Conoid backward.

**Actions.**—The movements of this articulation are of two kinds: 1. A gliding motion of the articular end of the clavicle on the acromion. 2. Rotation of the scapula forward and backward upon the clavicle, the extent of this rotation being limited by the two portions of the coraco-clavicular ligament.

The acromio-clavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Sir George Humphry that if there had been no joint between the clavicle and scapula the circular movement of the scapula on the ribs (as in throwing both shoulders backward or forward) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such position, and it would have been impossible to give a blow straight forward with the full force of the arm; that is to say, with the combined force of the scapula, arm, and forearm. “This joint,” as he happily says, “is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position or nearly so.” Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

**Surface Form.**—The position of the acromio-clavicular joint can generally be ascertained by the slightly enlarged extremity of the outer end of the clavicle, which causes it to project above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily to be felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

**Surgical Anatomy.**—Owing to the slanting shape of the articular surfaces of this joint, the commonest dislocation is the passing of the acromion process of the scapula under the outer end of the clavicle; but dislocations in the opposite direction have been described. The first form of dislocation is produced by violent force applied to the scapula so as to drive the shoulder forward. The displacement in acromio-clavicular dislocation is often incomplete, on account of the strong coraco-clavicular ligaments which remain untorn. The same difficulty exists, as in the sternoclavicular dislocation, in maintaining the ends of the bone in apposition after reduction, and it may become necessary to wire them in place after incision of the soft parts.

### III. Proper Ligaments of the Scapula (Figs. 219, 220).

The proper ligaments of the scapula pass between portions of that bone, but are not parts of an articulation. They are the

- **Coraco-acromial.**
- **Superior Transverse.**
- **Inferior Transverse.**

The **Coraco-acromial Ligament** (ligamentum coracoacromioid) is a strong triangular band, extending between the coracoid and acromial processes. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle, and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed inward, its anterior fibres forward and inward. This ligament completes the vault formed by the coracoid and acromion processes for the protection of the head of the humerus. It is in relation, above, with the clavicle and under surface of the Deltoid muscle; below, with the tendon of the Supraspinatus muscle, a bursa being interposed. Its outer border is continuous with a dense lamina that passes beneath the Deltoid upon the tendons
of the Supra- and Infraspinatus muscles. This ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as sometimes is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The Superior Transverse, Coracooid or Suprascapular Ligament (ligamentum transversum scapulae superius) (Figs. 219, 220, and 222) converts the suprascapular notch into a foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen; the suprascapular vessels pass over the ligament.

An additional ligament, the Inferior Transverse or Spino-glenoid Ligament (ligamentum transversum scapulae inferius), is sometimes found on the scapula, stretching from the outer border of the spine to the margin of the glenoid cavity. When present, it forms an arch under which the suprascapular vessels and nerve pass as they enter the infraspinous fossa.

Movements of Scapula.—The scapula is capable of being moved upward and downward, forward and backward, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which raise the scapula are the upper fibres of the Trapezius, the Levator anguli scapuli, and the two Rhomboids; those which depress it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn backward by the Rhomboids and the middle and lower fibres of the Trapezius, and forward

---

**Fig. 220.**—Right clavicle and shoulder-blade with ligament, from without and somewhat from in front. (Spalteholz.)
by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by
the Pectoralis major. The mobility of the scapula is very considerable, and
greatly assists the movements of the arm at the shoulder-joint. Thus, in raising
the arm from the side the Deltoid and Supraspinatus can only lift it to a right
angle with the trunk, the further elevation of the limb being effected by the
Trapezius and Serratus magnus moving the scapula on the wall of the chest.
This mobility is of special importance in ankylosis of the shoulder-joint, the
movement of this bone compensating to a very great extent for the immobility
of the joint.

IV. The Shoulder-joint (Articulatio Humeri) (Figs. 219, 220, 221, 222).

The shoulder is an enarthrodial or ball-and-socket joint. The bones entering
into its formation are the large globular head of the humerus, which is received
into the shallow glenoid cavity of the scapula—an arrangement which permits of
very considerable movement, whilst the joint itself is protected against displace-
ment by the tendons which surround it and by atmospheric pressure. The liga-
ments do not maintain the joint surfaces in apposition, because when they alone
remain the humerus can be separated to a considerable extent from the glenoid
cavity; their use, therefore, is to limit the amount of movement. Above, the joint
is protected by an arched vault, formed by the under surfaces of the coracoid
and acromion processes, and the coraco-acromial ligament. The articular surfaces
are covered by a layer of cartilage: that on the head of the humerus is thicker at
the centre than at the circumference, the reverse being the case in the glenoid
cavity. The ligaments of the shoulder are the

Capsular.
Coraco-humeral.

The Capsular Ligament (capsula articularis) (Figs. 219, 220, and 222) completely
encircles the articulation, being attached, above, to the circumference of the glenoid
cavity beyond the glenoid ligament, below, to the anatomical neck of the humerus,
approaching nearer to the articular cartilage above than in the rest of its extent.
It is thicker above and below than elsewhere, and is remarkably loose and lax, and

1 The long tendon of origin of the Biceps muscle also acts as one of the ligaments of this joint. See the
observations on p. 268 on the function of the muscles passing over more than one joint.
much larger and longer than is necessary to keep the bones in contact, allowing
them to be separated from each other more than an inch—an evident provision
for that extreme freedom of movement which is peculiar to this articulation. Its
superficial surface is strengthened, above, by the Supraspinatus; below, by the
long head of the Triceps; behind, by the tendons of the Infraspinatus and Teres
minor; and in front, by the tendon of the Subscapularis. The capsular ligament
usually presents three openings: One anteriorly, below the coracoid process,
establishes a communication between the synovial membrane of the joint and a
bursa beneath the tendon of the Subscapularis muscle. The second, which is
not constant, is at the posterior part, where a communication sometimes exists
between the joint and a bursal sac belonging to the Infraspinatus muscle. The
third is seen between the two tuberosities, for the passage of the long tendon
of the Biceps muscle. It transmits a sac-like prolongation of the synovial
membrane, which ends as a blind pouch opposite the surgical neck of the bone.
This synovial sac is called the vagina mucosa intertubercularis.

The Coraco-humeral Ligament (ligamentum coracohumerale) (Fig. 219) is a broad
band which strengthens the upper part of the capsular ligament. It arises from
the outer border of the coracoid process, and passes obliquely downward and out-
ward to the front of the great tuberosity of the humerus, being blended with the
tendon of the Supraspinatus muscle. This ligament is intimately united to the
capsular ligament throughout the greater part of its extent.

Supplemental Bands of the Capsular Ligament.—In addition to the coraco-
humeral ligament, the capsular ligament is strengthened by supplemental bands in
the interior of the joint. One of these bands is situated on the inner side of the
joint, and passes from the inner edge of the glenoid cavity to the lower part of the
lesser tuberosity of the humerus. This is sometimes known as Flood's ligament,
and is supposed to correspond with the ligamentum teres of the hip-joint. A
second of these bands is situated at the lower part of the joint, and passes from the
under edge of the glenoid cavity to the under part of the neck of the humerus, and
is known as Schlemm's ligament. A third, called the gleno-humeral ligament, is
situated at the upper part of the joint, and projects into its interior, so that it can be
seen only when the capsule is opened. It is attached above to the apex of the
glenoid cavity, close to the root of the coracoid process, and, passing downward
along the inner edge of the tendon of the Biceps, is attached below to the lesser
tuberosity of the humerus, where it forms the inner boundary of the upper part of the
bicipital groove. It is a thin, ribbon-like band, occasionally quite free from the
capsule.

The Transverse Humeral Ligament is a prolongation of the capsular ligament.
It is a broad band of fibrous tissue passing from the lesser to the greater tuber-
osity of the humerus, and always limited to that portion of the bone which lies
above the epiphysial line. It converts the bicipital groove into an osseo-aponen-
rotic canal, and is the analogue of the strong process of bone which connects the
summits of the two tuberosities in the musk ox.

The Glenoid Ligament (labrum glenoidale) (Figs. 220 and 222) is a fibro-
cartilaginous rim, attached round the margin of the glenoid cavity. It is trian-
gular on section, the thickest portion being fixed to the circumference of the cavity,
the free edge being thin and sharp. It is continuous above with the long tendon
of the Biceps muscle, which bifurcates at the upper part of the cavity into two
fasciculi, and becomes continuous with the fibrous tissue of the glenoid ligament.
This ligament deepens the cavity for articulation, and protects the edges of the
bone. It is lined by the synovial membrane.

Synovial Membrane (Fig. 222).—The synovial membrane is reflected from the
margin of the glenoid cavity over the fibro-cartilaginous rim surrounding it: it is
then reflected over the internal surface of the capsular ligament, covers the lower
part and sides of the anatomical neck of the humerus as far as the cartilage cover-
ing the head of the bone. The long tendon of the Biceps muscle which passes
through the capsular ligament is enclosed in a tubular sheath of synovial membrane
(vagina mucosa intertubercularis), which is reflected upon it at the point where it
perforates the capsule, and is continued around it as far as the level of the surgical
neck of the humerus. The tendon of the Biceps is thus enabled to traverse the
articulation, but it is not contained in the interior of the synovial cavity.

Bursa.—A large bursa exists between the joint capsule and the tendon of the
Subscapularis muscle. It is called the subscapular bursa. This sac communicates
with the shoulder-joint by means of an opening at the inner side of the capsular
ligament. The subscapular bursa is constant. Occasionally another and smaller
bursa exists beneath the tendon of the infraspinatus. It is called the infraspinatus
bursa, and communicates with the shoulder-joint by means of an opening in the outer
surface of the capsule. The subdeltoid or subacromial bursa is placed between the
under surface of the Deltoid muscle and the outer surface of the capsule. It does
not communicate with the joint. The subcutaneous acromial bursa is between the
surface and the summit of the acromion process. There is a bursa beneath
the Coraco-brachialis muscle—one beneath the teres major—and one beneath
the tendinous portion of the latissimus dorsi. There is also a bursa between the
tendon of insertion of the Pectoralis major muscle and the long head of the
biceps.

The Muscles in relation with the joint are, above, the Supraspinatus; below, the
long head of the Triceps; in front, the Subscapularis; behind, the Infraspinatus
and Teres minor; within, the long tendon of the Biceps. The Deltoid is placed
most externally, and covers the articulation on its outer side, as well as in front
and behind.
The Arteries supplying the joint are articular branches of the anterior and posterior circumflex, and the suprascapular.

The Nerves are derived from the circumflex and suprascapular.

Actions.—The shoulder-joint is capable of movement in every direction, forward, backward, abduction, adduction, circumduction, and rotation. The humerus is drawn forward by the Pectoralis major, anterior fibres of the Deltoid, Coraco-brachialis, and by the Biceps when the forearm is flexed; backward, by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and by the Triceps when the forearm is extended; it is abducted (elevated) by the Deltoid and Supraspinatus; it is adducted (depressed) by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major; it is rotated outward by the Infraspinatus and Teres minor; and it is rotated inward by the Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when supplemented by the glenoid ligament. 2. The looseness of the capsule of the joint. 3. The intimate connection of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the biceps tendon to the joint.

It is in consequence of the relative size of the two articular surfaces that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, they can be carried considerably farther by the movements of the scapula, involving, of course, motion at the acromio- and sterno-clavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint. The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown somewhat forward and outward, because the margin of the head of the humerus is by no means a true circle; its greatest diameter is from the bicapital groove downward, inward, and backward, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of the measurement. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoïd process, and the coraco-acromial ligament constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament and an opening made in it to remove the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere—an arrangement which “renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest” (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that “abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity, adduction by the tension of the coraco-humeral ligament” (Beaunis et Bouchard). Cleland maintains that the limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoid ligament fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

1 See p. 301. 2 Journal of Anatomy and Physiology, 1884, vol. xviii.
Cathcart¹ has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only from the hanging to the horizontal position, but also in passing upward as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—i.e., the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The intimate union of the tendons of the four short muscles with the capsule converts these muscles into elastic and spontaneously acting ligaments of the joint, and it is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subsurface various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously adverted to.² Next, it strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion process, when the Deltoid contracts, instead of forming the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infra-spinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coraco-acromial ligament, in a curved direction, with its convexity inward, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Surgical Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint in the body. Dislocations of the shoulder contribute about forty per cent. of the cases in tables of dislocations. Dislocation occurs when the arm is thrown into extreme abduction, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, between the tendon of the Subscapularis and the Triceps, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front and behind the joint. In consequence of the muscles at the back being weaker than those in front, and especially on account of the long head of the Triceps preventing the bone passing backward, dislocation forward is much more common than backward. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid dislocation. Occasionally, in consequence of a greater amount of force being brought to bear on the limb, the head is driven farther inward, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). If the head of the bone passes under the Subscapularis muscle and also under the Teres major or the lower border of the Pectoralis major, the arm remains abducted, or even with the elbow raised above the head (luxatio erecta). Sometimes the humerus remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (sub-

¹ Journal of Anatomy and Physiology, 1884, vol. xviii.
² See p. 208.
glenoid), and rarely it passes backward and remains in the infraspinatous fossa beneath the spine (subspinosus). If dislocation frequently recurs the condition may be amended in some cases by exposing the capsule and putting tucks in it by means of sutures.

An old unreduced dislocation is sometimes treated by incising the soft parts and returning the head of the humerus into the glenoid cavity. In other cases the head of the humerus is excised. Dislocation of the long tendon of the Biceps muscle from the bicipital groove is a rare accident. When it occurs the arm is rigid in abduction, but the head of the humerus is found to be in the glenoid cavity. It is reduced by flexion of the elbow and rotation of the arm. Rupture of the long tendon of the biceps is more common than dislocation of the tendon.

After this injury the belly of the muscle is relaxed and is nearer than normal to the elbow; flexion of the forearm is much weakened, and is weaker in supination than it is in pronation. The head of the humerus passes forward and inward, and the condition is often mistaken for dislocation of the bone.

If we desire to aspirate the shoulder-joint, place the arm against the side, flex the forearm at a right angle to the arm, carry the forearm across the front of the chest, and enter the trocar below the acromion (De Vos).

The shoulder-joint is sometimes the seat of all those inflammatory affections, both acute and chronic, which attack joints, though perhaps it suffers less frequently than some other joints of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyemia, or may follow secondarily on the so-called acute epiphyseitis of infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended and the contour of the joint rounded. Special projections may occur at the site of the openings in the capsular ligament. Thus a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis muscle; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major muscles, from effusion into the diverticulum, which runs down the bicipital groove with the tendon of the biceps. The effusion into the synovial membrane can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt. The bursa beneath the deltoïd is sometimes ruptured by violence, and sometimes inflames, suppures, or becomes tuberculous.

Tuberculous arthritis not infrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteoarthritis, and may also be affected in gout and rheumatism; or in locomotor ataxia, when it occasionally becomes the seat of Charcot’s disease.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coraco-aerial licencement down the arm for about three inches: this will expose the bicipital groove and the tendon of the Biceps, which may be either divided or hooked out of the way, according as to whether it is implicated in the disease or not. The capsule is then freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus divided. The head of the bone can then be thrust out of the wound and sawn off, or divided with a narrow saw in situ and subsequently removed. The section should be made; if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if carious.

V. The Elbow-joint (Articulatio Cubiti) (Figs. 223, 224, 225, 226).

The elbow is a ginglymus or hinge-joint. The bones entering into its formation are the trochlea of the humerus, which is received into the greater sigmoid cavity of the ulna (articulatio humeroulnaris), and admits of the movements peculiar to this joint—viz., flexion and extension; whilst the capitellum or radial head of the humerus articulates with the cup-shaped depression on the head of the radius (articulatio humeroradialis); the circumference of the head of the radius articulates with the lesser sigmoid cavity of the ulna (articulatio radio-ulnaris proximalis), allowing of the movement of rotation of the radius on the ulna, the chief action of the superior radio-ulnar articulation. The articular surfaces are covered with a thin layer of cartilage, and connected together by a capsular ligament (capsula articularis) (Fig. 225) of unequal thickness, being especially thickened on its two sides and, to a less extent, in front and behind.
These thickened portions are usually described as distinct ligaments under the following names:

- Anterior.
- Internal Lateral.
- Posterior.
- External Lateral.

The orbicular ligament of the upper radio-ulnar articulation must also be reckoned among the ligaments of the elbow.

The Anterior Ligament (Fig. 223) is a broad and thin fibrous layer which covers the anterior surface of the joint. It is attached to the front of the internal condyle and to the front of the humerus immediately above the coronoid and radial fossae; below, to the anterior surface of the coronoid process of the ulna and to the orbicular ligament, being continuous on each side with the lateral ligaments. Its superficial fibres pass obliquely from the inner condyle of the humerus outward to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but are mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the Brachialis anticus muscle, except at its outermost part; behind, it is in relation with the synovial membrane.

The Posterior Ligament (Fig. 224) is a thin and loose membranous fold, attached, above, to the lower end of the humerus. above and at the sides of the olecranon
fossa; below, to the groove on the upper and outer surfaces of the olecranon. The superficial or transverse fibres pass between the adjacent margins of the olecranon fossa. The deeper portion consists of vertical fibres, some of which, thin and weak, pass from the upper part of the olecranon fossa to the margin of the olecranon; others, thicker and stronger, pass from the back of the capitellum of the humerus to the posterior border of the lesser sigmoid cavity of the ulna. This ligament is in relation, behind, with the tendon of the Triceps muscle and the Anconeus muscle; in front, with the synovial membrane.

The Internal Lateral Ligament (ligamentum collaterale ulnare) (Fig. 223) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The anterior portion, directed obliquely forward, is attached, above, by its apex, to the front part of the internal condyle of the humerus; and, below, by its broad base, to the inner margin of the coronoid process. The posterior portion, also of triangular form, is attached, above, by its apex, to the lower and back part of the internal condyle; below, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal condyle to blend with a transverse band of ligamentous tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the Triceps and Flexor carpi ulnaris muscles and the ulnar nerve, and gives origin to part of the Flexor sublimis digitorum muscle.

The External Lateral Ligament (ligamentum collaterale radiale) (Fig. 224) is a short and narrow fibrous band less distinct than the internal, attached, above, to a depression below the external condyle of the humerus; below, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the ulna. This ligament is intimately blended with the tendon of origin of the Supinator brevis muscle.

Synovial Membrane (Fig. 225).—The synovial membrane is very extensive. It covers the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossa on that bone; from these points it is reflected over the anterior, posterior, and lateral ligaments, and forms a pouch (recessus sacciformis) between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the
circumference of the head of the radius. Projecting into the cavity is a crescentic fold of synovial membrane, between the radius and ulna, suggesting the division of the joint into two: one the humero-radial, the other the humero-ulnar.

Between the capsular ligament and the synovial membrane are three masses of fat: one, the largest, above the olecranon fossa, which is pressed into the fossa by the Triceps during flexion; a second, over the coronoid fossa; and a third, over the radial fossa. The two last-named pads are pressed into their respective fossae during extension.

The muscles (Fig. 226) in relation with the joint are, in front, the Brachialis anticus; behind, the Triceps and Anconeus; externally, the Supinator brevis and the common tendon of origin of the Extensor muscles; internally, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris, with the ulnar nerve.

The arteries supplying the joint are derived from the anastomosis between the superior profunda, inferior profunda, and anastomotica magna, branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar and the recurrent branch of the radial. These vessels form a complete chain of inosculation around the joint.

The nerves are derived from the ulnar as it passes between the internal condyle and the olecranon; a filament from the musculo-cutaneous (Rüdinger), and two filaments from the median (Macalister).

Bursæ.—The olecranon bursa (bursa subcutaneous olecrani) is placed between the olecranon process and the cutaneous surface. A bursa exists between the tendon of the Biceps and the tubercle of the radius (bursa bicicipitoradialis) — another between the Triceps tendon and the olecranon process (bursa subtendinea olecrani) — another between the cutaneous surface and the external condyle (bursa subcutanea epicondylæ humeri lateralis) — another between the cutaneous surface and the internal condyle (bursa subcutanea epicondylæ humeri medialis) — another within the Triceps tendon at its insertion on the olecranon (bursa intratendinea olecrani).

Actions.—The elbow-joint comprises three different portions—viz., the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radio-ulnar articulation, described below. All these articular surfaces are invested by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take
place in a straight line; so that when the forearm is extended and supinated the axis of the arm and forearm is not in the same line, but the one portion of the limb forms an angle with the others, and the hand, with the forearm, is directed outward. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the articular surface of the humerus, with its prominences and depressions accurately adapted to the opposing surfaces of the olecranon, prevents any lateral movement. Flexion is produced by the action of the Biceps and Brachialis anticus, assisted by the muscles arising from the internal condyle of the humerus and the Supinator longus; extension, by the Triceps and Anconeus, assisted by the extensors of the wrist and by the Extensor communis digitorum and Extensor minimi digitii.

The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodioid joint. The bony surfaces would of themselves constitute an enarthrosis, and allow of movement in all directions were it not for the orbicular ligament by which the head of the radius is bound down firmly to the sigmoid cavity of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise constantly occur as a consequence of the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament the tendon of the biceps would be liable to pull the head of the radius out of the joint.1 In complete extension the head of the radius glides so far back on the outer condyle that its edge is plainly felt at the back of the articulation. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint, the limitation of flexion being also aided by the soft structures of the arm and forearm coming in contact.

In combination with any position of flexion or extension the head of the radius can be rotated in the upper radio-ulnar joint, carrying the hand with it. The hand is directly articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint (as will be seen in the sequel) by the interarticular fibro-cartilage. Thus, rotation of the head of the radius round an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Surface Form.—If the forearm be slightly flexed on the arm, a curved crease or fold with its convexity downward may be seen running across the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position of the radio-humeral portion of the joint can be at once ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

Surgical Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, lateral displacement of the bones is very uncommon, whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, much more frequently takes place, dislocation backward taking place when the forearm is in a position of extension, and forward when in a position of flexion. For, in the former position, that of extension, the coronoid process is not interlocked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forward. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backward, while the olecranon loses its grip and is not so efficient, as during extension, in preventing a forward displacement. When lateral dislocation does take place, it is generally incomplete.

1 Humphry, op cit., p. 419.
Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation, for, as a rule, fracture of a bone more frequently takes place, under the application of any severe violence, in young persons than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury. Sprain of the elbow is a very common injury in childhood. Injury to the radio-humeral joint is frequently produced by lifting a child by the hand, as in swinging it over a gutter. The supinator brevis, which under normal circumstances would retain the head of the radius against the capitellum of the humerus, is unable to do so, the radio-humeral articulation receives the force and the orbicular ligament undergoes upward displacement, is caught between the head of the radius and the capitellum and jams the joint. This injury is often called subluxation of the head of the radius.

The elbow-joint is occasionally the seat of acute synovitis. The synovial membrane then becomes distended with fluid, the bulging showing itself principally around the olecranon process; that is to say, on its inner and outer sides and above, in consequence of the laxness of the posterior ligament. Occasionally a well-marked, triangular projection may be seen on the outer side of the olecranon, from bulging of the synovial membrane beneath the Anconeus muscle. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint. There is generally not much swelling at the front of the joint, though sometimes deep-seated fullness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps muscle; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus muscle. Chronic synovitis, usually of tuberculous origin, is of common occurrence in the elbow-joint: under these circumstances the forearm tends to assume the position of semi-flexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind that should ankylosis occur in this or the extended position, the limb will not be nearly so useful as if it becomes ankylosed in a position of rather less than a right angle. Loose cartilages are sometimes met with in the elbow-joint, not so commonly, however, as in the knee; nor do they, as a rule, give rise to such urgent symptoms. They rarely require operative interference. The elbow-joint is also sometimes affected with osteo-arthritis, but this affection is less common in this articulation than in some other of the larger joints. Bursitis about the elbow is not uncommon. Enlargement of the subcutaneous bursa over the olecranon is known as miners' elbow. Enlargement of any one of the bursae may occur.

Excision of the elbow is principally required for one of three conditions—viz., tuberculous arthritis, injury and its results, and ankylosis in a position which greatly impairs the usefulness of the limb; but may be necessary for some other rarer conditions, such as disorganizing arthritis after pyaemia, unreduced dislocation, and osteo-arthritis. The results of the operation are, as a rule, more favorable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in the first three of the conditions mentioned above. The operation is best performed by a single vertical incision down the back of the joint, a transverse incision, over the outer condyle, being added if the parts are much thickened and fixed. A straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps muscle. The operator with the point of his knife, and guarding the soft parts with his thumb-nail, separates them from the bone. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process, and the prolongation of the Triceps into the deep fascia of the forearm over the Anconeus muscle. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bone turned out and sawn off. The section of the humerus should be through the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such fibrous union as shall allow free motion of the bones of the forearm; and, therefore, passive motion must be commenced early, that is to say, about the tenth day.

VI. Radio-ulnar Articulation (Articulatio Radioulnaris).

The articulation of the radius with the ulna is effected by ligaments which connect together both extremities as well as the shafts of these bones. It may, consequently, be subdivided into three articulations: (1) the superior radio-ulnar, which is a portion of the elbow-joint; (2) the middle radio-ulnar; and (3) the inferior radio-ulnar articulations.

1 Mr. Jonathan Hutchinson, Jr., in Annals of Surgery, August, 1885.
1. Superior or Proximal Radio-ulnar Articulation (Articulatio Radioulnaris Proximalis).

This articulation is a trochoid or pivot-joint. The bones entering into its formation are the inner side of the circumference of the head of the radius rotating within the lesser sigmoid cavity of the ulna. Its only ligament is the annular or orbicular.

The Orbicular or Annular Ligament (ligamentum annulare radii) (Figs. 223, 224, and 227) is a strong, flat band of ligamentous fibres which surrounds the head of the radius and retains it in firm connection with the lesser sigmoid cavity of the ulna. It forms about four-fifths of an osseo-fibrous ring, attached by each end to the extremities of the lesser sigmoid cavity, and is smaller at the lower part of its circumference than above, by which means the head of the radius is more securely held in its position. Its outer surface is strengthened by the external lateral ligament of the elbow, and affords origin to part of the Supinator brevis muscle. Its inner surface is smooth, and lined by synovial membrane. The synovial membrane is continuous with that which lines the elbow-joint.

Actions.—The movement which takes place in this articulation is limited to rotation of the head of the radius within the orbicular ligament, and upon the lesser sigmoid cavity of the ulna, rotation forward being called pronation; rotation backward, supination. Supination is performed by the Biceps and Supinator brevis, assisted to a slight extent by the Extensor muscles of the thumb and, in certain positions, by the Supinator longus. Pronation is performed by the Pronator radii teres and the Pronator quadratus, assisted, in some positions, by the Supinator longus.

Surface Form.—The position of the superior radio-ulnar joint is marked on the surface of the body by the little dimple on the back of the elbow which indicates the position of the head of the radius.

Surgical Anatomy.—Dislocation of the head of the radius alone is not an uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downward or the orbicular ligament upward, and the upper border of the ligament becomes folded over the head of the radius, between it and the capitulum of the humerus.

2. Middle Radio-ulnar Ligaments.

The interval between the shafts of the radius and ulna is occupied by two ligaments.

Oblique. Interosseous.

The Oblique or Round Ligament (chorda obliqua) (Figs. 223 and 225) is a small, flattened fibrous band which extends obliquely downward and outward from the tubercle of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the interosseous ligament, and it appears to be placed as a substitute for it in the upper part of the interosseous interval. This ligament is sometimes wanting.

The Interosseous Membrane (membrana interossea antibrachii) (Fig. 227) is a broad and thin plane of fibrous tissue descending obliquely downward and inward, from the interosseous ridge on the radius to that on the ulna. It is deficient above, commencing about an inch beneath the tubercle of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones and to increase the extent of surface for the attachment of the deep muscles. Between its upper
border and the oblique ligament an interval exists through which the posterior interosseous vessels pass to the dorsum of the forearm. Two or three fibrous bands are occasionally found on the posterior surface of this membrane which descend obliquely from the ulna toward the radius, and which have consequently a direction contrary to that of the other fibres. It is in relation, in front, by its upper three-fourths with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying upon the interval between which are the anterior interosseous vessels and nerve; by its lower fourth, with the Pronator quadratus; behind, with the Supinator brevis, Extensor ossis metacarpi pollicis, Extensor brevis pollicis, Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

3. Inferior or Distal Radio-ulnar Articulation (Articulatio Radioularnaris Distalis).

This is a pivot-joint, formed by the sigmoid cavity at the inner side of the lower end of the radius receiving the head of the ulna. The articular surfaces are covered by a thin layer of cartilage, and connected together by a capsule (capsula articularis), portions of which are usually described as distinct ligaments. The ligaments of the articulation are:

- Anterior Radio-ulnar.
- Posterior Radio-ulnar.
- Triangular Interarticular Fibro-cartilage.

The Anterior Radio-ulnar Ligament (Fig. 228) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

The Posterior Radio-ulnar Ligament (Fig. 229) extends between similar points on the posterior surface of the articulation.

The Triangular Interarticular Fibro-cartilage (discus articularis) (Figs. 227 and 231) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower end of this bone and the radius firmly together. Its periphery
is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of

the radius, which separates the sigmoid cavity from the carpal articulating surface. Its margins are united to the ligaments of the wrist-joint. Its upper surface, smooth and concave, articulates with the head of the ulna, forming an

arthrodial joint; its under surface, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform and inner part of the semilunar bone. Both surfaces are lined by a synovial membrane—the upper surface, by
one peculiar to the radio-ulnar articulation; the under surface, by the synovial membrane of the wrist.

Synovial Membrane.—The synovial membrane (Fig. 231) of this articulation has been called, from its extreme looseness, the membrana sacciformis. It projects horizontally inward between the head of the ulna and the interarticular fibro-cartilage, and upward between the radius and the ulna, forming a very loose cul-de-sac (recessus sacciformis). The quantity of synovia which it contains is usually considerable. The inferior radio-ulnar joint does not communicate with the wrist-joint.

Actions.—The movement in the inferior radio-ulnar articulation is just the reverse of that in the superior radio-ulnar joint. It consists of a movement of rotation of the lower end of the radius round an axis which corresponds to the centre of the head of the ulna. When the radius rotates forward, pronation of the forearm and hand is the result; and when backward, supination. It will thus be seen that pronation and supination of the forearm and hand the radius describes a segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement, however, the ulna is not quite stationary, but rotates a little in the opposite direction. So that it also describes the segment of a cone, though of smaller size than that described by the radius. The movement which causes this alteration in the position of the head of the ulna takes place principally at the shoulder-joint by a rotation of the humerus, but possibly also to a slight extent at the elbow-joint.¹

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

VII. Radio-carpal or Wrist-joint (Articulatio Radiocarpea) (Figs. 228, 229, 231).

The wrist is a condyloid articulation. The parts entering into its formation are the lower end of the radius and under surface of the interarticular fibro-cartilage, which form together the receiving cavity, and the scaphoid, semilunar, and the cuneiform bones, which form the condyle. The articular surface of the radius and the under surface of the interarticular fibro-cartilage are the receiving cavity, forming together a transversely elliptical concave surface. The articular surfaces of the scaphoid, semilunar, and cuneiform bones form together a smooth, convex surface, the condyle, which is received into the concavity above mentioned. All the bony surfaces of the articulation are covered with cartilage, and

¹ See Journal of Anatomy and Physiology, vol. xix., parts ii., iii., and iv.
connected together by a loose capsule (capsula articularis), which is divided into the following ligaments:

<table>
<thead>
<tr>
<th>External Lateral.</th>
<th>Anterior.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Internal Lateral.</td>
<td>Posterior.</td>
</tr>
</tbody>
</table>

The **External Lateral Ligament** (ligamentum collaterale carpi radiale) (Fig. 228) extends from the summit of the styloid process of the radius to the outer side of the scaphoid, some of its fibres being prolonged to the trapezium and annular ligament.

The **Internal Lateral Ligament** (ligamentum collaterale carpi ulnare) (Fig. 228) is a rounded cord, attached, above, to the extremity of the styloid process of the ulna, and dividing below into two fascieuli, which are attached, one to the inner side of the cuneiform bone, the other to the pisiform bone and annular ligament.

The **Anterior or Volar Ligament** (ligamentum radiocarpeum volare) (Fig. 228) is a broad, membranous band, attached, above, to the anterior margin of the lower end of the radius, its styloid process, and the ulna; its fibres pass downward and inward to be inserted into the palmar surface of the scaphoid, semilunar, and cuneiform bones, some of the fibres being continued to the os magnum. In addition to this broad membrane there is a distinct rounded fasciculus, superficial to the rest, which passes from the base of the styloid process of the ulna to the semilunar and cuneiform bones. This ligament is perforated by numerous apertures for the passage of vessels, and is in relation, in front, with the tendons of the Flexor profundus digitorum and Flexor longus pollicis; behind, with the synovial membrane of the wrist-joint.

The **Posterior or Dorsal Ligament** (ligamentum radiocarpeum dorsale) (Fig. 229), less thick and strong than the anterior, is attached, above, to the posterior border of the lower end of the radius; its fibres pass obliquely downward and inward, to be attached to the dorsal surface of the scaphoid, semilunar, and cuneiform bones, being continuous with those of the dorsal carpal ligaments. This ligament is in relation, behind, with the extensor tendons of the fingers; in front, with the synovial membrane of the wrist.

**Synovial Membrane.**—The synovial membrane (Fig. 231) lines the inner surface of the ligaments above described, extending from the lower end of the radius and interarticular fibro-cartilage above to the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

**Relations.**—The wrist-joint is covered in front by the flexor and behind by the extensor tendons (Fig. 230); it is also in relation with the radial and ulnar arteries.

The arteries supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The nerves are derived from the ulnar and posterior interosseous.

**Actions.**—The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. Its actions will be further studied with those of the carpus, with which they are combined.

**Surface Form.**—The line of the radio-carpal joint is on a level with the apex of the styloid process of the ulna.

**Surgical Anatomy.**—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movement which takes place between the several bones serves to break the jars that result from falls or blows on the hand. Dislocation backward, which is the more common dislocation, simulates to a considerable extent Colles's fracture of the radius, and is liable to be mistaken for it. The diagnosis can be easily made out by observing the relative position of the styloid processes of the radius and the ulna. In the natural condition
the styloid process of the radius is on a lower level—i.e., nearer the ground—when the arm hangs by the side, than that of the ulna, and the same would be the case in dislocation. In Colles's fracture, on the other hand, the styloid process of the radius is on the same or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis, the result of traumatism or arising in the rheumatic or pyemic state. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighborhood. Chronic inflammation of the wrist is generally tuberculous, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, often leads to necrosis of the carpal bones, and the result is often unsatisfactory.

VIII. Articulations of the Carpus (Articulatio Intercarpea) (Figs. 228, 229, 231).

These articulations may be subdivided into three sets:

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. Articulations of the First Row of Carpal Bones.

These are arthrodiol joints. The ligaments connecting the scaphoid, semilunar, and cuneiform bones are—

Dorsal. Palmar.

Two Interosseous

The Dorsal Ligaments (ligamenta intercarpea dorsalia) are placed transversely behind the bones of the first row; they connect the scaphoid and semilunar and the semilunar and cuneiform.

The Palmar or Volar Ligaments (ligamenta intercarpea volaria) connect the scaphoid and semilunar and the semilunar and cuneiform bones; they are less strong than the dorsal, and placed very deeply below the anterior ligament of the wrist.

The Interosseous Ligaments (ligamenta intercarpea interossea) (Fig. 231) are two narrow bundles of fibrous tissue connecting the semilunar bone on one side with the scaphoid, and on the other with the cuneiform. They are on a level with the superior surfaces of these bones, and close the upper part of the spaces between them. Their upper surfaces are smooth, and form with the bones the convex articular surfaces of the wrist-joint.

The ligaments connecting the pisiform bone are—

Capsular. Palmar.

Two Palmar Ligaments.

The Capsular Ligament (capsula articularis) is a thin membrane which connects the pisiform bone to the cuneiform. It is lined with a separate synovial membrane.

The Two Palmar Ligaments are two strong fibrous bands which connect the pisiform to the unciform, the piso-uncinate ligament (ligamentum pisohamatum), and to the base of the fifth metacarpal bone, the piso-metacarpal ligament (ligamentum pisometacarpeum).

2. Articulations of the Second Row of Carpal Bones.

These are also arthrodiol joints. The articular surfaces are covered with cartilage, and connected by the following ligaments:

Dorsal. Palmar.

Three Interosseous.
The Dorsal Ligaments (ligamenta intercarpea dorsalia) extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The Palmar or Volar Ligaments (ligamenta intercarpea volaria) have a similar arrangement on the palmar surface.

The Three Interosseous Ligaments (ligamenta intercarpea interossea) (Fig. 231) much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting.

3. Articulations of the Two Rows of Carpal Bones with Each Other (Figs. 228, 229, 231).

The joint between the scaphoid, semilunar, and cuneiform, and the second row of the carpus, or the mid-carpal joint, is made up of three distinct portions; in the centre the head of the os magnum and the superior surface of the unciform articulate with the deep, cup-shaped cavity formed by the scaphoid and semilunar bones, and constitute a sort of ball-and-socket joint. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming gliding joints.

The ligaments are:

<table>
<thead>
<tr>
<th>Anterior.</th>
<th>External Lateral.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Posterior.</td>
<td>Internal Lateral.</td>
</tr>
</tbody>
</table>

The Anterior, Palmar, or Volar Ligaments (ligamenta intercarpea volaria) consist of short fibres, which pass, for the most part, from the palmar surface of the bones of the first row to the front of the os magnum.

The Posterior or Dorsal Ligaments (ligamenta intercarpea dorsalia) consist of short, irregular bundles of fibres passing between the bones of the first and second row on the dorsal surface of the carpus.

The Lateral Ligaments are very short: they are placed, one on the radial, the other on the ulnar side of the carpus; the former, the stronger and more distinct, connecting the scaphoid and trapezium bones; the latter the cuneiform and unciform; they are continuous with the lateral ligaments of the wrist-joint. In addition to these ligaments, a slender interosseous band sometimes connects the os magnum and the scaphoid.

Synovial Membrane (Fig. 231).—The synovial membrane of the carpus is very extensive: it passes from the under surface of the scaphoid, semilunar, and cuneiform bones to the upper surface of the bones of the second row, sending upward two prolongations—between the scaphoid and semilunar and the semilunar and cuneiform; sending downward three prolongations between the four bones of the second row, which are further continued onward into the carpo-metacarpal joints of the four inner metacarpal bones, and also for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and cuneiform bones.

Actions.—The articulation of the hand and wrist, considered as a whole, is divided into three parts: (1) the radius and the interarticular fibro-cartilage; (2) the meniscus, formed by the scaphoid, semilunar, and cuneiform, the pisiform bone having no essential part in the movements of the hand; (3) the hand proper, the metacarpal bones with the four carpal bones on which they are supported—viz., the trapezium, trapezoid, os magnum, and unciform. These three elements form two joints: (1) the superior, wrist-joint proper, between the meniscus and bones of the forearm; (2) the inferior, between the hand and meniscus, transverse or mid-carpal joint.
(1) The articulation between the forearm and carpus is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than flexion is permitted on account of the articulating surfaces extending farther on the dorsal than on the palmar aspect of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. Of these the former is considerably greater in extent than the latter. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the consecutive movements of adduction, extension, abduction, and flexion, with intermediate movements between them. There is no rotation, but this is provided for by the supination and pronation of the radius on the ulna. The movement of flexion is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; extension, by the Extensor carpi radialis longior et brevior and the Extensor carpi ulnaris; adduction (ulnar flexion), by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and abduction (radial flexion), by the Extensors of the thumb and the Extensor carpi radialis longior et brevior and the Flexor carpi radialis.

(2) The chief movements permitted in the transverse or mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which is the movement most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forward and backward on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the os magnum rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

IX. Carpo-metacarpal Articulations (Articulationes Carpometacarpeae)
(Figs. 228, 229, 231).

1. Articulation of the Metacarpal Bone of the Thumb with the Trapeziun (Articulatio Carpometacarpea Pollicis).

This is a joint of reciprocal reception, and enjoys great freedom of movement, on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, each bone appears to be received into a cavity in the other, according to the direction in which they are cut. The joint is surrounded by a capsular ligament.

The Capsular Ligament (capsula articularis) is thick and fibrous, but loose, and passes from the circumference of the upper extremity of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest externally and behind, and lined by a separate synovial membrane.

Movements.—In the articulation of the metacarpal bone of the thumb with the trapezium the movements permitted are flexion, extension, adduction, abduction, and circumduction. When the joint is flexed the metacarpal bone is brought in front of the palm and the thumb is gradually turned to the fingers. It is by this peculiar movement that the tip of the thumb is opposed to the other digits; for by slightly flexing the fingers the palmar surface of the thumb can be brought in contact with their palmar surfaces one after another.
2. Articulations of the Metacarpal Bones of the Four Inner Fingers with the Carpus (Articulationes Carpometacarpae).

The joints formed between the carpus and four inner metacarpal bones are arthrodial joints. The ligaments are—

Dorsal.  
Interosseous.  
Palmar.

The Dorsal Ligaments (ligamenta carpometacarpea dorsalia), the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surface.

The second metacarpal bone receives two fasciculi—one from the trapezium, the other from the trapezoid; the third metacarpal receives two—one from the trapezoid and one from the os magnum; the fourth two—one from the os magnum and one from the unciform; the fifth receives a single fasciculus from the unciform bone, which is continuous with a similar ligament on the palmar surface, forming an incomplete capsule.

The Palmar or Volar Ligaments (ligamenta carpometacarpea volaria) have a somewhat similar arrangement on the palmar surface, with the exception of the third metacarpal, which has three ligaments—an external one from the
trapezium, situated above the sheath of the tendon of the Flexor carpi radialis; a middle one, from the os magnum; and an internal one, from the unciform.

The **Interosseous Ligaments** consist of short, thick fibres, which are limited to one part of the carpo-metacarpal articulation; they connect the contiguous inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

**Synovial Membrane.**—The synovial membrane is a continuation of that between the two rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (Fig. 231) are thus seen to be five in number. The *first*, the membrana sacciformis or the recessus sacciformis of the inferior radio-ulnar articulation, passes from the lower end of the ulna to

![Fig. 232. Metacarpal bones and first phalanges of the second to the fifth finger of the right hand, with ligaments, from the volar surface. (Spalteholz.)](image)

the sigmoid cavity of the radius, and lines the upper surface of the interarticular fibro-cartilage. The *second* passes from the lower end of the radius and inter-articular fibro-cartilage above to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones—between the bones of the second row to the carpal extremities of the four inner metacarpal bones. The *fourth*, from the margin of the trapezium to the metacarpal bone of the thumb. The *fifth*, between the adjacent margins of the cuneiform and pisiform bones.

**Actions.**—The movement permitted in the carpo-metacarpal articulations of the four inner fingers is limited to a slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus the articulation of the metacarpal bone of the little finger is most movable, then that of the ring finger. The metacarpal bones of the index and middle fingers are almost immovable.
3. Articulations of the Metacarpal Bones with Each Other (Articulationes Intermetacarpae) (Figs. 228, 229, 231).

The carpal extremities of the four inner metacarpal bones articulate with one another at each side by small surfaces covered with cartilages, and connected together by dorsal, palmar, and interosseous ligaments.

The Dorsal Ligaments (ligamenta basium oss. metacarp. dorsalia) and Palmar Ligaments (ligamenta basium oss. metacarp. volaria) pass transversely from one bone to another on the dorsal and palmar surfaces.

The Interosseous Ligaments (ligamenta basium oss. metacarp. interossea) pass between their contiguous surfaces, just beneath their lateral articular facets.

Synovial Membrane (Fig. 231).—The synovial membrane between the lateral facets is a reflection from that between the two rows of carpal bones.

The Transverse Metacarpal Ligament (ligamentum capitulorum oss. metacarpalium transversum) (Fig. 232) is a narrow, fibrous band which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them together. It is blended anteriorly with the palmar ligaments of the metacarpo-phalangeal articulations. To its posterior border is connected the fascia which covers the Interossei muscles. Its anterior surface is concave where the flexor tendons pass over it. Behind it the tendons of the Interossei muscles pass to their insertion.

X. Metacarpo-phalangeal Articulations (Articulationes Metacarpo-phalangae) (Figs. 232, 233).

These articulations are of the condyloid kind, formed by the reception of the rounded head of the metacarpal bone into a shallow cavity in the extremity of the first phalanx. The expansion of the extensor tendon acts as a dorsal ligament. There is a capsular ligament which at certain points has strengthening ligaments. The ligaments are—

Anterior. Two Lateral.

The Anterior, Palmar, or Vaginal Ligament (glenoid ligament of Cruveilhier, ligamentum vaginale) is a thick, dense, fibrous structure, placed on the palmar surface of the joint in the interval between the lateral ligaments, to which it is connected; it is loosely united to the metacarpal bone, but very firmly to the base of the first phalanx. Its palmar surface is intimately blended with the transverse metacarpal ligament, and presents a
groove for the passage of the flexor tendons, the sheath surrounding which is connected to each side of the groove. By its deep surface it forms part of the articular surface for the head of the metacarpal bone, and is lined by a synovial membrane.

The Lateral or Collateral Ligaments (ligamenta collateralia) are strong, rounded cords placed one on each side of the joint, each being attached by one extremity to the posterior tubercle on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

*Actions.*—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the lateral movements are very limited.

*Surface Form.*—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpo-phalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle. The usual rule for finding these joints is to flex the distal phalanx on the proximal one to a right angle; the position of the joint is then indicated by an imaginary line drawn along the middle of the lateral aspect of the proximal phalanx.

**XI. Articulations of the Phalanges (Articulationes Digitorum Manus)** (Fig. 233).

These are ginglymus joints. Each joint has a capsule, and certain accentuated portions are regarded as definite ligaments. These ligaments are—

Anterior or Palmar. Two Lateral (ligamenta collateralia).

The arrangement of these ligaments is similar to those in the metacarpo-phalangeal articulations; the extensor tendon supplies the place of a dorsal ligament.

*Actions.*—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

**ARTICULATIONS OF THE LOWER EXTREMITY.**

The articulations of the Lower Extremity comprise the following groups:

I. The Hip-joint. VI. The Tarso-metatarsal Articulations.
II. The Knee-joint. VII. Articulations of the Metatarsal Bones with each other.
III. The Articulations between the VIII. The Metatarso-phalangeal Articulations.
   Tibia and Fibula. IX. The Articulations of the Phalanges.
IV. The Ankle-joint.  
V. The Articulations of the Tarsus.  

I. The Hip-joint (Articulatio Coxa) (Figs. 234, 235, 236, 237, 238, 239).

This articulation is an enarthrodial or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articulating surfaces are covered with cartilage, that on the head of the femur being thicker at the centre than at the circumference, and covering the entire surface, with the exception of a depression just below its centre for the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference. It forms an incomplete cartilaginous ring of a horseshoe shape, being deficient below, where there is a circular depression, which is occu-
The articulations or joints

pied in the recent state by a mass of fat covered by synovial membrane. The ligaments of the joints are the

Capsular.  
Ilio-femoral.  
Transverse.

Teres.  
Cotyloid.

The Capsular Ligament (capsula articularis) (Figs. 234, 235, 237, and 239) is a strong, dense, ligamentous capsule, embracing the margin of the acetabulum above and surrounding the neck of the femur below. Its upper circumference is attached to the acetabulum, above and behind, two or three lines external to the cotyloid ligament; but in front it is attached to the outer margin of this ligament, and opposite to the notch, where the margin of this cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. Its lower circumference surrounds the neck of the femur, being attached, in front, to the spiral or anterior intertrochanteric line; above, to the base of the neck; behind, to the neck of the bone, about half
an inch above the posterior intertrochanteric line. From this insertion the fibres are reflected upward over the neck of the femur, forming a sort of tubular sheath, the *cervical reflection*, which blends with the periosteum and can be traced as far as the articular cartilage. On the surface of the neck of the femur some of these reflected fibres are raised into longitudinal folds, termed *retinacula*. It is much thicker at the upper and forepart of the joint, where the greatest amount of

![Diagram of the hip joint](image)

Fig. 235.—Right hip-joint, from behind. (The joint capsule, except for the strengthening ligaments, has been removed.) (Spalteholz.) resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular fibres, *zona orbicularis* (Fig. 237), are most abundant at the lower and back part of the capsule, and form a sling or collar around the neck of the femur. Anteriorly they blend with the deep surface of the ilio-femoral ligament, and through its medium reach the anterior inferior spine of the ilium. The longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they form distinct bands or accessory ligaments, of which the most important is the *ilio-femoral*. Other accessory bands are known as the *pubo-
The **iliofemoral** or **Y-ligament** or **Ligament of Bigelow** (*ligamentum ilio-femorale*) (Figs. 234, 235, 237, and 238) is an accessory band of fibres extending obliquely across the front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, above, to the lower part of the anterior inferior spine of the ilium and the adjacent rim of the acetabulum; and, diverging below, forms two bands, of which one passes downward to be inserted into the lower part of the anterior intertrochanteric line; the other passes downward and outward to be inserted into the upper part of the same line and the adjacent part of the neck of the femur. Between the two bands is a thinner part of the capsule. Sometimes there is no division, but the ligament spreads out into a flat, triangular band, which is attached below into the whole length of the anterior intertrochanteric line. This ligament is frequently called the **Y-shaped ligament of Bigelow**; and
THE HIP-JOINT

329

the outer or upper of the two bands is sometimes described as a separate ligament, under the name of the ilio-trochanteric ligament.

The Ligamentum Teres, or the Interarticular Ligament (ligamentum teres femoris) (Figs. 236, 237, and 239) is a triangular band implanted by its apex into the depression a little behind and below the centre of the head of the femur, and by its broad base into the margins of the cotyloid notch, becoming blended with the transverse ligament. It is formed of connective tissue, surrounded by a tubular sheath of synovial membrane. Sometimes only the synovial fold exists. Very rarely it is absent. The ligament is made tense when the hip is semiflexed,

![Diagram of the hip joint](image)

and the limb adducted and rotated outward; it is, on the other hand, relaxed when the limb is abducted. It has, however, but little influence as a ligament, though it may to a certain extent limit movement, and would appear to be merely a "vestigial and practically useless ligament." It is probably a modification of the folds which in other joints fringe the margins of reflection of synovial membranes.

The Cotyloid Ligament (labrum glenoidale) (Fig. 239) is a fibro-cartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the

---

same time it protects the edges of the bone and fills up the inequalities on its surface. It bridges over the notch as the transverse ligament of the acetabulum, and thus forms a complete circle, which closely surrounds the head of the femur, and assists in holding it in its place, acting as a sort of valve. It is prismoid on section, its base being attached to the margin of the acetabulum and its opposite edge being free and sharp; whilst its two surfaces are invested by synovial membrane, the external one being in contact with the capsular ligament, the internal one being inclined inward, so as to narrow the acetabulum and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front, and consists of close, compact fibres, which arise from different points of the circumference of the acetabulum and interlace with each other at very acute angles.

The transverse ligament of the acetabulum (ligamentum transversum acetabuli) (Figs. 236 and 239) is in reality a portion of the cotyloid ligament, though differing from it in having no cartilage-cells amongst its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

Synovial Membrane (Figs. 237 and 239).—The synovial membrane is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum, and is prolonged in the form of a tubular sheath around the ligamentum teres, as far as the head of the femur. It sometimes communicates through a hole in the capsular ligament between the inner band of the Y-shaped ligament and the pubo-femoral ligament with a bursa situated on the under surface of the Ilio-psosas muscle.

The muscles in relation with the joint (Fig. 240) are, in front, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; above, the reflected head of the Rectus and Gluteus minimus, the latter being closely adherent to the capsule; internally, the Obturator externus and Pectineus; behind, the Pyiformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris.

The arteries supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The nerves are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the anterior crural supplying the rectus.

Bursæ.—Numerous bursæ exist in the neighborhood of the hip-joint. Some anatomists have counted twenty-one (Symmestredt). The chief ones are: 1. The ilio-pectineal bursa (bursa iliopectinea) (Fig. 240), between the ilio-psosas tendon and the capsule of the joint. It often communicates with the hip-joint. 2. The
The hip joint consist of the gluteus maximus muscle and the greater trochanter of the femur.

3. The subcutaneous trochanteric bursa (bursa trochanterica subcutanea), between the cutaneous surface and the great trochanter. Besides these there is a bursa between the great trochanter and the anterior part of the Gluteus medius—between the great trochanter and the posterior part of the Gluteus medius—between the great trochanter and the Gluteus minimus—beneath the Pyriformis muscle—between the small trochanter and the Quadratus femoris muscle, and there are bursae beneath the Biceps femoris muscle.

**Actions.**—The movements of the hip are very extensive, and consist of flexion, extension, adduction, abduction, circumduction, and rotation.
The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as we have seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The anterior portion of the capsule, described as the ilio-femoral ligament, is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and

Therefore the pelvis tends to fall backward, but is prevented by the tension of the ilio-femoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. Flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact when the leg is flexed on the thigh; and by the action of the hamstring muscles when the leg is extended; extension, by the tension of the ilio-femoral ligament and front of the capsule; adduction, by the thighs coming into contact; adduction, with flexion by the outer band of the ilio-femoral ligament, the outer part of the capsular ligament;

1 The hip-joint cannot be completely flexed, in most persons, without at the same time flexing the knee, on account of the shortness of the hamstring muscles.—Cleland, Jour. of Anat. and Phys., No. 1, Old Series, p. 87.
abduction, by the inner band of the ilio-femoral ligament and the pubo-femoral band; rotation outward, by the outer band of the ilio-femoral ligament; and rotation inward, by the ischio-capsular ligament and the hinder part of the capsule. The muscles which \textbf{flex} the femur on the pelvis are the Psoas, Iliacus, Rectus, Sartorius, Pectineus, Adductor longus and brevis, and the anterior fibres of the Gluteus medius and minimus. \textbf{Extension} is mainly performed by the Gluteus maximus, assisted by the hamstring muscles. The thigh is \textbf{adducted} by the Adductor magnus, longus, and brevis, the Pectineus, the Gracilis, and lower part of the Gluteus maximus, and \textbf{abducted} by the Gluteus medius and minimus and upper part of the Gluteus maximus. The muscles which \textbf{rotate} the thigh \textbf{inward} are the anterior fibres of the Gluteus medius, the Gluteus minimus, and the Tensor fascia femoris; while those which rotate it \textbf{outward} are the posterior fibres of the Gluteus medius, the Pyriformis, Obturator externus and internus, Gemellus superior and inferior, Quadratus femoris, Iliacus, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

\textbf{Surface Form.}—A line drawn from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium (Nélaton's line) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; or, in other words, the upper border of the great trochanter, which lies on Nélaton's line, is on a level with the centre of the hip-joint.

\textbf{Surgical Anatomy.}—\textbf{Inflammation of bursa} about the hip-joint gives rise to confusing symptoms. Inflammation of one of the bursae over the great trochanter is not uncommon. Great pain is produced if any movement of the gluteal muscles is permitted. \textbf{Enlargement of the bursa} over the ischiial tuberosity was long called \textbf{weaver's button}. Enlargement of the bursa beneath the ilio-psoas may produce a large swelling. \textbf{Bursal inflammation} is not unusually mistaken for hip-joint disease.

\textbf{In dislocation of the hip} "the head of the thigh bone may rest at any point around its socket" (Bryant); but whatever position the head ultimately assumes, the primary displacement is generally downward and inward, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the ilio-femoral ligament, which is not easily ruptured. When, for instance, the head is forced backward, this ligament forms a fixed axis, round which the head of the bone rotates, and the head is thus driven on to the dorsum of the ilium. The ilio-femoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backward it is tense, and produces inversion of the limb; in the dislocation on to the pubes it is relaxed, and therefore allows the external rotators to evert the thigh; while in the thyroid dislocation it is tense and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. But Bigelow has endeavored to show that the Obturator internus is the principal agent in determining whether in the backward dislocations the head of the bone shall be ultimately lodged on the dorsum of the ilium or in or near the sciatic notch. In both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the displacement on to the dorsum, the head of the bone travels up behind the acetabulum, in front of the muscle; while in the dislocation into the sciatic notch, the head passes behind the muscle, and is therefore prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and so remains in the neighborhood of the sciatic notch. Bigelow, therefore, distinguishes these two forms of dislocation by describing them as dislocations backward, "above and below," the Obturator internus.

The ilio-femoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as a fulcrum to a lever, of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of \textbf{acute synovitis} from injury, on account of its deep position and its thick covering of soft parts. \textbf{Acute inflammation} may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyæmia, etc. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the ilio-femoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much more frequently of a chronic character and is usually of \textbf{tuberculous} origin. It begins either in the bones or in the synovial membrane, more frequently in the
II. The Knee-joint (Articulatio Genu).

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: one between each condyle of the femur and the corresponding tuberosity of the tibia, which are condyloid joints, and one between the patella and the femur, which is partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals.
where three synovial membranes are sometimes found, corresponding to these three subdivisions, either entirely distinct or only connected together by small communications. This view is further rendered probable by the existence of the two crucial ligaments within the joint, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the ligamentum mucosum would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each joint.

The bones entering into the formation of the knee-joint are the condyles of the femur above, the head of the tibia below, and the patella in front. The bones are connected together by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

**External Ligaments.**
- Anterior, or Ligamentum Patellæ.
- Posterior.
- Internal Lateral.
- Two External Lateral. (The long external ligament is constant. The short external ligament is not always present.)
- Capsular.

**Interior Ligaments.**
- Anterior, or External Crucial.
- Posterior, or Internal Crucial.
- Two Semilunar Fibro-cartilages.
- Transverse.
- Coronary.
- Ligamentum mucosum.
- Processes of Ligamenta alaria.
- Synovial Membrane.

The **Anterior Ligament, or Ligamentum Patellæ** (Figs. 241, 245, and 246), is the central portion of the common tendon of the Extensor muscles of the thigh, which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band about three inches in length, attached, above, to the apex of the patella and the rough depression on its posterior surface; below, to the lower part of the tubercle of the tibia, its superficial fibres being continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles pass down on either side of the patella, and are attached to the borders of this bone. The deep fascia and the quadriceps extensor muscle are inserted into the patella. Prolongations from the fascia and from the fibrous expansion of the muscle pass from the edges of the patella and from the ligament of the patella to the upper extremity of the tibia on each side of the tubercle; externally, and to the head of the fibula. They are termed **lateral patellar ligaments** *(retinaculum patellæ mediale and retinaculum patellæ laterale)*, and merge into the capsule. The posterior surface of the ligamentum patellae is separated from the front of the capsular ligament by a mass of fat.

The **Posterior Ligament** *(ligamentum popliteum obliquum)* (Fig. 241) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached, above, to the upper margin of the intercondylar notch of the femur, and, below, to the posterior margin of the head of the tibia. Superficial to the main part of the ligament and forming a portion of it is a strong fasciculus derived from the tendon of the Semimembranosus, and passing from the back part of the inner tuberosity of the tibia obliquely upward and outward to the back part of the outer condyle of the femur. This expansion from the tendon of the Semimembranosus muscle is called the **posterior ligament of Winslow** *(ligamentum posticum Winslowit)*, and it merges with the posterior ligament. The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

The **Internal Lateral Ligament** *(ligamentum collateral tibiale)* (Figs. 241 and 242) is a broad, flat, membranous band, thicker behind than in front, and situated
nearer to the back than the front of the joint. It is attached, above, to the inner tuberosity of the femur; below, to the inner tuberosity and inner surface of the shaft of the tibia to the extent of about two inches. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semitendinosus muscles, a synovial bursa being interposed. Its deep surface covers the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres, the synovial membrane of the joint, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibro-cartilage.

Fig. 241.—Right knee-joint. Anterior view. Fig. 242.—Right knee-joint. Posterior view.

The External Lateral or Long External Lateral Ligament (ligamentum collaterale fibulare) (Figs. 242 and 246) is a strong, rounded, fibrous cord situated nearer to the back than the front of the joint. It is attached, above, to the back part of the outer tuberosity of the femur; below, to the outer part of the head of the fibula. Its outer surface is covered by the tendon of the Biceps, which divides at its insertion into two parts, separated by the ligament. The ligament has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The Short External Lateral Ligament (ligamentum laterale externum breve seu posticum) (Fig. 242) is not a constant structure. It is an accessory bundle of fibres placed behind and parallel with the preceding, attached, above, to the lower and back part of the outer tuberosity of the femur; below, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular ligament, and has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.
The Capsular Ligament (capsula articularis) (Fig. 241) consists of an exceedingly thin but strong, fibrous membrane which fills in the intervals left between the stronger bands above described, and is inseparably connected with them. In front it blends with and forms part of the lateral patellar ligaments and fills in the interval between the anterior and lateral ligaments of the joints, with which latter structures it is closely connected. It is deficient above the joint and beneath the tendon of the quadriceps extensor. Behind, it is formed chiefly of vertical fibres, which arise above from the condyles and intercondyloid notch of the femur, and is connected below with the back part of the head of the tibia, being closely united with the origins of the Gastrocnemius, Plantaris, and Popliteus muscles. It passes in front of, but is inseparably connected with, the posterior ligament.

The Crucial Ligaments (ligamenta cruciata genu) (Figs. 171, 243, and 244) are two interosseous ligaments of considerable strength situated in the interior of the joint, nearer its posterior than its anterior part. They are called crucial because they cross each other somewhat like the lines of the letter X; and have received the names anterior crucial and posterior crucial, from the position of their attachment to the tibia.

The anterior or external crucial ligament (ligamentum cruciatum anterius) (Fig. 243) is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibro-cartilage, and, passing obliquely upward, backward, and outward, is inserted into the inner and back part of the outer condyle of the femur.

The posterior or internal crucial ligament (ligamentum cruciatum posterius) is stronger, but shorter and less oblique in its direction than the anterior. It is attached to the back part of the depression behind the spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibro-cartilage; and passes upward, forward, and inward, to be inserted into the outer and forepart of the inner condyle of the femur. It is in relation, in front, with the anterior crucial ligament; behind, with the capsular ligament.

The Semilunar Fibro-cartilages (menisic) (Figs. 171, 243, 244, 245, and 246) are two crescentic lamellae which serve to deepen the surface of the head of the tibia, for articulation with the condyles of the femur. The
circumference of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the inner border is thin, concave, and free. Their upper surfaces are concave, and in relation with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia. Each cartilage covers nearly the outer two-thirds of the corresponding articular surface of the tibia, leaving the inner third uncovered; both surfaces are smooth and invested by synovial membrane.

The internal semilunar fibro-cartilage (meniscus medialis) is nearly semicircular in form, a little elongated from before backward, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is attached to the depression behind the spine, between the attachments of the external semilunar fibro-cartilage and the posterior crucial ligaments.
The external semilunar fibro-cartilage (meniscus lateralis) forms nearly an entire circle, covering a larger portion of the articular surface than the internal one. It is grooved on its outer side for the tendon of the Popliteus muscle. Its extremities, at their insertion, are interposed between the two extremities of the internal semilunar fibro-cartilage; the anterior extremity being attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the posterior extremity being attached behind the spine of the tibia, in front of the posterior extremity of the internal semilunar fibro-cartilage. Just before its insertion posteriorly it gives off a strong fasciculus, the ligament of Wrisberg, which passes obliquely upward and outward, to be inserted into the inner condyle of the femur, close to the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off which passes forward to be inserted into the back part of the anterior crucial ligament. The
external semilunar fibro-cartilage gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The Transverse Ligament (ligamentum transversum genu) (Fig. 244) is a band of fibres which passes transversely from the anterior convex margin of the external semilunar fibro-cartilage to the anterior convex margin of the internal semilunar fibro-cartilage; its thickness varies considerably in different subjects, and it is sometimes absent altogether.

The Coronary Ligaments (ligamenta coronaria) are merely portions of the capsular ligament, which connect the circumference of each of the semilunar fibro-cartilages with the margin of the head of the tibia.

Synovial Membrane (Figs. 245 and 246).—The synovial membrane encloses the articular cavity (cavum articulare) of the knee-joint. It is the largest and most extensive synovial membrane in the body. Commencing above the upper border of the patella, it forms a short cul-de-sac beneath the Quadriceps extensor tendon of the thigh, on the lower part of the front of the shaft of the femur; this communicates, by an orifice of variable size, with a synovial bursa interposed between the tendon and the front of the femur (bursa suprapatellaris). On each side of the patella the synovial membrane extends beneath the aponeurosis of the Vasti muscles, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by the anterior part of the capsule and a considerable quantity of adipose tissue, known as the infrapatellar pad (Fig. 245). In this situation the synovial membrane sends off a triangular prolongation, containing a few ligamentous fibres, which extends from the anterior part of the joint below the patella to the front of the intercondylar notch. This fold has been termed the ligamentum mucosum (plica synovialis patellaris). It also sends off two fringe-like folds, called the ligamenta alaria (plicae alares) (Fig. 245), which extend from the sides of the ligamentum mucosum, upward and laterally between the patella and femur. On either side of the joint it passes downward from the femur, lining the capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and from thence along their under surfaces to the tibia. At the back part of the external one it forms a cul-de-sac between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments and lines the inner surface of the ligaments which enclose the joint. The pouch of synovial membrane between the Extensor tendon and front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into the upper part of the capsular ligament.

The folds of synovial membrane and the fatty processes contained in them act, as it seems, mainly in padding to fill up interspaces and obviate concussions. Sometimes the bursa beneath the Quadriceps extensor is completely shut off from the rest of the synovial cavity, thus forming a closed sac between the Quadriceps and the lower part of the front of the femur; sometimes it communicates with the synovial cavity by a minute aperture; usually the two cavities are incompletely separated by a synovial fold.

Bursæ.—The bursæ about the knee-joint are the following: In front there are four bursæ: one is interposed between the patella and the skin. It is known as the prepatellar bursa (bursa prepatellaris subcutanea); another, of small size, between the upper part of the tuberosity of the tibia and the ligamentum patellæ is called the deep infrapatellar bursa (bursa infrapatellaris profunda); and a third between the lower part of the tuberosity of the tibia and the skin, the subcutaneous tibial bursa (bursa subcutanea tuberositatis tibiae). A fourth bursa exists in front, the suprapatellar bursa (bursa suprapatellaris). It lies between the anterior surface of the lower end of the femur and the posterior surface of the quadriceps femoris. Spalteholz says that the supra-
patellar bursa is closely connected with the quadriceps tendon and is usually incompletely shut off from the cavity of the joint. Occasionally there is a bursa between the expansion of the fascia lata and the Quadriceps and the patella (bursa prepatellaris subfascialis), and sometimes one between the tendon of the quadriceps and the anterior surface of the patella (bursa prepatellaris subtendinea). On the outer side there are four bursae: (1) one beneath the outer head of the Gastrocnemius (which sometimes communicates with the joint); (2) one above the external lateral ligament between it and the tendon of the Biceps; (3) one beneath the external lateral ligament between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus (bursa musculi poplitei) between it and the condyle of the femur, which is almost always an extension from the synovial membrane of the joint. On the inner side there are five bursae: (1) one beneath the inner head of the Gastrocnemius, which sends a prolongation between the tendons of the Gastrocnemius and Semimembranosus: this bursa often communicates with the joint; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one beneath the internal lateral ligament between it and the tendon of the Semimembranosus: this is sometimes only an expansion from the next bursa; (4) one beneath the tendon of the Semimembranosus, between it and the head of the tibia; (5) sometimes there is a bursa between the tendons of the Semimembranosus and of the Semitendinosus.

Structures around the Joint.—In front and at the sides, the Quadriceps extensor; on the outer side, the tendons of the Biceps and the Popliteus and the external popliteal nerve; on the inner side, the Sartorius, Gracilis, Semitendinosus, and Semimembranosus; behind, an expansion from the tendon of the Semimembranosus, the popliteal vessels, and the internal popliteal nerve, the Popliteus, the Plantaris, and the inner and outer heads of the Gastrocnemius, some lymphatic glands, and fat.

The arteries supplying the joint are derived from the anastomotica magna branch of the femoral, articular branches of the popliteal, anterior and posterior recurrent branches of the anterior tibial, and a descending branch from the external circumflex of the Profunda.

The nerves are derived from the obturator, anterior crural, and external and internal popliteal.

Actions.—The knee-joint permits of movements of flexion and extension, and, in certain positions, of slight rotation inward and outward. The movement of flexion and extension does not, however, take place in a simple, finger-like manner, as in other joints, but is a complicated movement, consisting of a certain amount of gliding and rotation; so that the same part of one articular surface is not always applied to the same part of the other articular surface, and the axis of motion is not a fixed one. If the joint is examined while in a condition of extreme flexion, the posterior part of the articular surfaces of the tibia will be found to be in contact with the posterior rounded extremities of the condyles of the femur; and if a simple hinge-like movement were to take place, the axis, round which the revolving movement of the tibia occurs, would be in the back part of the condyle. If the leg is now brought forward into a position of semi-flexion, the upper surface of the tibia will be seen to glide over the condyles of the femur, so that the middle part of the articular facets are in contact, and the axis of rotation must therefore have shifted forward to nearer the centre of the condyles. If the leg is now brought into the extended position, a still further gliding takes place and a further shifting forward of the axis of rotation. This

---

is not, however, a simple movement, but is accompanied by a certain amount of
rotation outward round a vertical axis drawn through the centre of the head of
the tibia. This rotation is due to the greater length of the internal condyle, and
to the fact that the anterior portion of its articular surface is inclined obliquely
outward. In consequence of this it will be seen that toward the close of the
movement of extension—that is to say, just before complete extension is effected
—the tibia glides obliquely upward and outward over this oblique surface on the
inner condyle, and the leg is therefore necessarily rotated outward. In flexion
of the joint the converse of these movements takes place: the tibia glides backward
round the end of the femur, and at the commencement of the movement the tibia
is directed downward and inward along the oblique curve of the inner condyle,
thus causing an inward rotation to the leg.

During flexion and extension the patella moves on the lower end of the femur,
but this movement is not a simple gliding one; for if the articular surface of this
bone is examined, it will be found to present on each side of the central vertical
ridge two less marked transverse ridges, which divide the surface, except a small
portion along the inner border, which is cut off by a slight vertical ridge into
six facets (see Fig. 247), and therefore does not present a uniform curved surface
as would be the case if a simple gliding movement took place. These six facets—three on each side of the
median vertical ridge—correspond to and denote the parts of the bone respectively in contact with the con-
dyles of the femur during flexion, semiflexion, and exten-
sion. In flexion only the upper facets on the patella are
in contact with the condyles of the femur; the lower
two-thirds of the bone rests upon the mass of fat which
occupies the space between the femur and tibia. In the
semiflexed position of the joint the middle facets on the
patella rest upon the most prominent portion of the con-
dyles, and thus afford greater leverage to the Quadriiceps
by increasing its distance from the centre of motion. In
complete extension the patella is drawn up, so that only
the lower facets are in contact with the articular sur-
faces of the condyles. The narrow strip along the inner border is in contact
with the outer aspect of the internal condyle when the leg is fully flexed at
the knee-joint. As in the elbow, so it is in the knee—the axis of rotation in
flexion and extension is not precisely at right angles to the axis of the bone, but
during flexion there is a certain amount of alteration of plane; so that, whereas in
flexion the femur and tibia are in the same plane, in extension the one bone forms
an angle of about 10 degrees with the other. There is, however, this difference
between the two extremities: that in the upper, during extension, the humeri are
parallel and the bones of the forearm diverge; in the lower, the femora converge
below and the tibia are parallel.

In addition to the slight rotation during flexion and extension, the tibia enjoys
an independent rotation on the condyles of the femur in certain positions of the
joint. This movement takes place between the interarticular fibro-cartilages and
the tibia, whereas the movement of flexion and extension takes place between the
interarticular fibro-cartilages and the femur. So that the knee may be said to
consist of two joints, separated by the fibro-cartilages: an upper, menisco-femoral,
in which flexion and extension take place; and a lower, menisco-tibial, allowing of
a certain amount of rotation. This latter movement can only take place in the
semiflexed position of the limb, when all the ligaments are relaxed.

During flexion the ligamentum patellae is put upon the stretch, as is also the
posterior crucial ligament in extreme flexion. The other ligaments are all relaxed
by flexion of the joint, though the relaxation of the anterior crucial ligament is very trifling. During life flexion is checked by the contact of the leg with the thigh. In the act of extending the leg upon the thigh the ligamentum patellae is tightened by the Quadriceps extensor; but when the leg is fully extended, as in the erect posture, the ligament becomes relaxed, so as to allow free lateral movement to the patella, which then rests on the front of the lower end of the femur. The other ligaments, with the exception of the posterior crucial, which is partly relaxed, are all on the stretch. When the limb has been brought into a straight line, extension is checked mainly by the tension of all the ligaments except the posterior crucial and ligamentum patellae. The movements of rotation of which the knee is capable are permitted in the semiflexed condition by the partial relaxation of both crucial ligaments, as well as of the lateral ligaments. Rotation inward appears to be limited by the tension of the anterior crucial ligament, and by the interlocking of the two ligaments; but rotation outward does not appear to be checked by either crucial ligament, since they uncross during the execution of this movement, but it is checked by the lateral ligaments, especially the internal. The main function of the crucial ligaments is to act as a direct bond of union between the tibia and femur, preventing the former bone from being carried too far backward or forward. Thus the anterior crucial ligament prevents the tibia being carried too far forward by the extensor tendons, and the posterior crucial checks too great movement backward by the flexors. They also assist the lateral ligaments in resisting any lateral bending of the joint. The interarticular cartilages are intended, as it seems, to adapt the surface of the tibia to the shape of the femur to a certain extent, so as to fill up the intervals which would otherwise be felt in the varying positions of the joint, and to interrupt the jars which would be so frequently transmitted up the limb in jumping or falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface during kneeling the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor muscle when it acts upon the tibia; and Mr. Ward has pointed out how this leverage varies in the various positions of the joint, so that the action of the muscles produces velocity at the expense of force in the commencement of extension, and, on the contrary, at the close of extension tends to diminish velocity, and therefore the shock to the ligaments at the moment tension of the structures takes place.

Extension of the leg on the thigh is performed by the Quadriceps extensor; flexion by the hamstring muscles, assisted by the Gracilis and Sartorius, and, indirectly, by the Gastrocnemius, Popliteus, and Plantaris; rotation outward, by the Biceps; and rotation inward by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis.

Surface Form.—The interval between the two bones entering into the formation of the knee-joint can always easily be felt. If the limb is extended, it is situated on a slightly higher level than the apex of the patella; but if the limb is slightly flexed, a knife carried horizontally backward immediately below the apex of the patella would pass directly into the joint. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Surgical Anatomy.—The bursa about the knee are frequently the seat of inflammation. Enlargement of the prepatellar bursa constitutes housemaid's knee. The bursa beneath the Semimembranosus may enlarge greatly. It communicates with the knee-joint and can frequently be made to disappear by pressure when the knee is flexed. Treves points out that enlargement of the bursa between the biceps tendon and the external lateral ligament causes great pain because the peroneal nerve crosses the sac.²

From a consideration of the construction of the knee-joint it would at first sight appear to be

---

1 Human Osteology, p. 405.
2 Applied Anatomy.
one of the least secure of any of the joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is very considerable; but, nevertheless, on account of the very powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumaism is of very rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is very liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated in any direction from the femur—forward, backward, inward, or outward; or a combination of two of these dislocations may occur—that is, the tibia may be dislocated forward and laterally, or backward and laterally, and any of these dislocations may be complete or incomplete. As a rule, however, the antero-posterior dislocations are complete, the lateral ones incomplete.

One or other of the semilunar cartilages may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inward or outward: that is to say, either inward toward the tibial spine, so that the cartilage becomes lodged in the intercondylar notch; or outward, so that the cartilage projects beyond the margin of the articular surface. Acute synovitis, the result of traumaism or exposure to cold, is very common in the knee, on account of its superficial position. When distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch or more above the trochlear surface of the femur, and extending a little higher under the Vastus internus than the Vastus externus. Occasionally the swelling may extend two inches or more. At the sides of the patella the swelling extends lower at the inner side than it does on the outer side. The lower level of the synovial membrane is just above the level of the upper part of the head of the fibula. In the middle line it covers the upper third of the ligamentum patellae, being separated from it, however, by the capsule and a pad of fat. Chronic synovitis principally shows itself in the form of pulpy degeneration of the synovial membrane, the result of tuberculous arthritis. The reasons why tuberculous disease of the knee so often commences in the synovial membrane appear to be the complex and extensive nature of this sac; the extensive vascular supply to it; and the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bones. Syphilitic disease not unfrequently attacks the knee-joint. In the hereditary form of the disease it is usually symmetrical, attacking both joints, which become filled with synovial effusion, and is very intractable and difficult to cure. In the tertiary stage of acquired syphilis gummatus infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilage is almost confined to the knee, though loose cartilages are occasionally met with in the elbow, and, rarely, in some other joints. Many of them occur in cases of osteo-arthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, "loose" cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

Genu valgum, or knock-knee, is a common deformity of childhood, in which, owing to changes in and about the joint, the angle between the outer border of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiae are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. To prevent this the internal condyle becomes depressed; probably, as was first pointed out by Mikulicz, by an increased growth of the lower end of the diaphysis on its inner side, so that the line of the epiphysis becomes oblique instead of transverse to the axis of the bone, with a direction downward and inward. It is often said that the deformity is produced by undue length of the inner condyle, but in reality the condyle grows as the deformity progresses.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practiced in cases of disorganization of the knee after rheumatic fever, pyemia, etc., in osteo-arthritis, and in ankylosis. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed either by a horseshoe incision, starting from one condyle, descending as low as the tubercle of the tibia, where it crosses the leg, and is then carried upward to the other condyle; or by a transverse incision across the patella. In this
latter incision the patella is either removed or sawn across, and the halves subsequently sutured together. The bones having been cleared, and in those cases where the operation is performed for tuberculous disease all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysial cartilage will be involved, with disastrous results as regards the growth of the limb. Afterward a thin slice should be removed from the upper end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge rather than by making a further section of the bones.

III. Tibio-fibular Articulation (Articulatio Tibiofibularis).

The articulations between the tibia and fibula are effected by ligaments which connect both extremities, as well as the shafts of the bones. It may, consequently, be subdivided into three articulations: 1. The superior tibio-fibular articulation. 2. The middle tibio-fibular ligament or interosseous membrane. 3. The inferior tibio-fibular articulation.

1. Superior Tibio-fibular Articulation (Articulatio Tibiofibularis).

This articulation is an arthrodial joint. The contiguous surfaces of the bones present two flat, oval facets covered with cartilage, and connected together by the following ligaments:

Capsular.
Anterior Superior Tibio-fibular.
Posterior Superior Tibio-fibular.

The Capsular Ligament (capsula articularis) consists of a membranous bag which surrounds the articulation, being attached around the margins of the articular facets on the tibia and fibula, and is much thicker in front than behind.

The new nomenclature considers the anterior and posterior ligaments as one ligament (ligamentum capituli fibulae).

The Anterior Superior Ligament (Fig. 248) consists of two or three broad and flat bands which pass obliquely upward and inward from the front of the head of the fibula to the front of the outer tuberosity of the tibia.

The Posterior Superior Ligament (Fig. 241) is a single thick and
broad band which passes upward and inward from the back part of the head of the fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.

**Synovial Membrane.**—A synovial membrane lines this articulation, which at its upper and back part is occasionally continuous with that of the knee-joint.

2. **Middle Tibio-fibular Ligament or Interosseous Membrane (Membrana Interossea Cruris) (Fig. 248).**

An interosseous membrane extends between the contiguous margins of the tibia, and fibula and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres which for the most part pass downward and outward between the interosseous ridges on the two bones; some few fibres, however, pass in the opposite direction, downward and inward. It is broader above than below. Its upper margin does not quite reach the superior tibio-fibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels forward to the anterior aspect of the leg. At its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament, and is perforated in numerous places for the passage of small vessels. It is in relation, in front, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; behind, with the Tibialis posticus and Flexor longus hallucis.

3. **Inferior Tibio-fibular Articulation (Syndesmosis Tibiofibularis) (Figs. 250, 251, 252).**

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, connected with a concave rough surface on the outer side of the tibia. Below, to the extent of about two lines, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are—

Anterior Inferior Tibio-fibular. Transverse or Inferior.
Posterior Inferior Tibio-fibular. Inferior Interosseous.

The **Anterior Inferior Ligament** (*ligamentum malleoli lateralis antierius*) (Figs. 248 and 252) is a flat, triangular band of fibres, broader below than above, which extends obliquely downward and outward, between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in front, with the Peroneus tertius, the aponeurosis of the leg, and the integument; behind, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The **Posterior Inferior Ligament** (*ligamentum malleoli lateralis posteriorius*) (Fig. 252), smaller than the preceding, is disposed in a similar manner on the posterior surface of the articulation.

The **Transverse Ligament** or **Inferior Ligament** lies under cover of the posterior ligament, and is a strong, thick band of yellowish fibres which passes transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The **Inferior Interosseous Ligament** (Fig. 250) consists of numerous short, strong, fibrous bands which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. This ligament is continuous above with the interosseous membrane.
Synovial Membrane.—The synovial membrane lining the articular surface is derived from that of the ankle-joint (Fig. 250).

Actions.—The movement permitted in these articulations is limited to a very slight gliding of the articular surfaces one upon another.

IV. The Tibio-tarsal Articulation or Ankle-joint (Articulatio Talocruralis) (Figs. 249, 250, 251, 252).

The ankle is a ginglymus or hinge-joint. The bones entering into its formation are the lower extremity of the tibia and its malleolus and the external malleolus of the fibula, which forms a mortise (Fig. 248) to receive the upper convex surface of the astragalus and its two lateral facets. The bony surfaces are covered with cartilage and connected together by a capsule (capsula articularis), which in places forms thickened bands constituting the following ligaments:

Anterior. Internal Lateral.
Posterior. External Lateral.

The Anterior Tibio-tarsal Ligament (ligamentum talotibiale anterius) is a broad, thin, membranous layer, attached, above, to the anterior margin of the lower extremity of the tibia; below, to the margin of the astragalus, in front of its articular surface. It is in relation, in front, with the Extensor tendons of the toes, with the tendons of the Tibialis anticus and Peroneus tertius, and the anterior tibial vessels and nerve; behind, it lies in contact with the synovial membrane.

The Posterior Tibio-tarsal Ligament (ligamentum talotibiale posterius) is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament; below, to the astragalus, behind its superior articular facet. Externally, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus, it is thicker than internally.
The Internal Lateral or Deltoid Ligament (*ligamentum calcaneotibiale* or *ligamentum deltoideum*) (Figs. 249, 250, and 251) is a strong, flat, triangular band, attached, above, to the apex and anterior and posterior borders of the inner malleolus. The most anterior fibres pass forward to be inserted into the scaphoid bone and the inferior calcaneo-scaphoid ligament; the middle descend almost perpendicularly to be inserted into the sustentaculum tali of the os calcis; and the posterior fibres pass backward and outward to be attached to the inner side of the astragalus. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum muscles.

The External Lateral Ligament (*ligamenta talofibulare et calcaneofibulare*) (Figs. 251 and 252) consists of three distinctly specialized fasciculi of the capsule, taking different directions and separated by distinct intervals; for which reason it is described by some anatomists as three distinct ligaments.¹

The anterior fasciculus (*ligamentum talofibulare anterius*), the shortest of the three, passes from the anterior margin of the external malleolus forward and inward to the astragalus, in front of its external articular facet.

The posterior fasciculus (*ligamentum talofibulare posterius*), the most deeply seated, passes inward from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus. Its fibres are almost horizontal in direction.

The middle fasciculus (*ligamentum calcaneofibulare*) (Figs. 251 and 252), the longest of the three, is a narrow, rounded cord passing from the apex of the external malleolus downward and slightly backward to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peroneus longus and brevis.

**Synovial Membrane.**—The synovial membrane (Fig. 250) invests the inner surface of the ligaments, and sends a duplicature upward between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in front, from within outward, the Tibialis anticus, Extensor proprior hallucus, anterior tibial vessels, anterior tibial nerve, Extensor longus digitorum, and Peroneus tertius; behind, from within outward, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels, posterior tibial nerve, Flexor longus hallucus; and in the groove behind the external malleolus, the tendons of the Peroneus longus and brevis.

The arteries supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.
The nerves are derived from the anterior and posterior tibial.

**Actions.**—The movements of the joint are those of flexion and extension. Flexion consists in the approximation of the dorsum of the foot to the front of the leg, while in extension the heel is drawn up and the toes pointed downward. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibio-fibular ligaments and slight bending of the shaft of the fibula. Of the ligaments, the internal, or deltoid, is of very great power—so much so that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backward, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forward, and limits extension of the joint. The movements of inversion and eversion of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, etc., are mainly effected in the tarsal joints, the one which enjoys the greatest amount of motion being that between the astragalus and os calcis behind and the scaphoid and cuboid in front. This is often called the transverse or medio-tarsal joint, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the tarsal bones upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posticus, Peroneus longus and brevis, Flexor longus digitorum, and Flexor longus hallucis; flexion, by the Tibialis anticus, Peroneus tertius, Extensor longus digitorum, and Extensor proprius hallucis

---

1. The student must bear in mind that the Extensor longus digitorum and Extensor proprius hallucis are extensors of the toes, but flexors of the ankle, and that the Flexor longus digitorum and Flexor longus hallucis are flexors of the toes, but extensors of the ankle.
(Fig. 251); inversion, in the extended position, is produced by the Tibialis anticus and posticus; and eversion by the Peronei.

Surface Form.—The line of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus.

Surgical Anatomy.—Displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of common occurrence, as the ankle-joint is a very strong and powerful articulation, and great force is required to produce dislocation. Nevertheless, dislocation does occasionally occur, both in an antero-posterior and a lateral direction. In the latter, which is the most common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation round an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upward, is inclined more or less inward or outward according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the tibialis anticus and the internal lateral ligament on the inner side, and between the Peroneus tertius and the external lateral ligament on the outer side. In addition to this, bulging frequently occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo Achillis.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; chronic synovitis may be tuberculous in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence as a synovitis the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed for two reasons. In the first place, disease of the articulation for which this operation is indicated is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is frequently of very little use; far less, in fact, than after a Syme’s amputation, which is often, therefore, a preferable operation in these cases. Excision may, however, be attempted in a case of tuberculous arthritis in a young and otherwise healthy subject, where the disease is limited to the bones forming the joint. It may also be required after injury where the vessels and nerves have not been damaged and the patient is young and free from visceral disease. The excision is best performed through two lateral incisions. One commencing two and a half inches above the external malleolus, carried down the posterior border of the fibula, round the end of the bone, and then forward and downward as far as the calcaneo-cuboid joint, midway between the tip of the external malleolus and the tuberosity on the fifth metatarsal bone. Through this incision
the fibula is cleared, the external lateral ligament is divided, and the bone sawn through about half an inch above the level of the ankle-joint and removed. A similar curved incision is now made on the inner side of the foot, commencing two and a half inches above the lower end of the tibia, carried down the posterior border of the bone, round the internal malleolus, and forward and downward to the tuberosity of the scaphoid bone. Through this incision the tibia is cleared in front and behind, the internal lateral, the anterior and posterior ligaments divided, and the end of the tibia protruded through the wound by displacing the foot outward, and sawn off sufficiently high to secure a healthy section of bone. The articular surface of the astragalus is now to be sawn off or the whole bone removed. In cases where the operation is performed for tuberculous arthritis the latter course is probably preferable, as the injury done by the saw is frequently the starting point of fresh caries; and after removal of the whole bone the shortening is not appreciably increased, and the result as regards union appears to be as good as when two sawn surfaces of bone are brought into apposition.

V. Articulations of the Tarsus (Articulationes Intertarseæ) (Figs. 249, 251, 252, 254, 255).

1. Articulation of the Os Calcis and Astragalus or the Calcaneo-astragaloid Articulation (Articulatio Talocalcanea) (Fig. 251).

The articulations between the os calcis and astragalus are two in number— anterior and posterior. They are arthrodiad joints. The bones are connected together by a capsule (capsula articularis), which is at certain points accentuated into definite ligaments. There are five ligaments in this articulation:

- External Calcaneo-astragaloid.
- Anterior Calcaneo-astragaloid.
- Internal Calcaneo-astragaloid.
- Posterior Calcaneo-astragaloid.
- Interosseous.

The External Calcaneo-astragaloid Ligament (ligamentum talocalcaneum laterale) (Fig. 252) is a short, strong, fasciculus passing from the outer surface of the astragalus, immediately beneath its external malleolar facet, to the outer surface of the os calcis. It is placed in front of the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

The Internal Calcaneo-astragaloid Ligament (ligamentum talocalcaneum mediale) is a band of fibres connecting the internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneo-scaphoid ligament.

The Anterior Calcaneo-astragaloid Ligament (ligamentum talocalcaneum anterius) passes from the front and outer surface of the neck of the astragalus to the superior surface of the os calcis.

The Posterior Calcaneo-astragaloid Ligament (ligamentum talocalcaneum posterius) connects the external tubercle of the astragalus with the upper and inner part of the os calcis; it is a short band, the fibres of which radiate from their narrow attachment to the astragalus.

The Interosseous Ligament (ligamentum talocalcaneum interosseum) (Figs. 250, 251, and 255) forms the chief bond of union between the bones. It consists of numerous vertical and oblique fibres attached by one extremity to the groove between the articulating facets on the under surface of the astragalus; by the other to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

Synovial Membrane.—The synovial membranes (Fig. 255) are two in number: one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid joint. The latter synovial membrane is continued forward between the contiguous surfaces of the astragalus and scaphoid bones.
ARTICULATIONS OF THE TARSUS

353

Actions.—The movements permitted between the astragalus and os calcis are limited to a gliding of the one bone on the other in a direction from before backward, and from side to side.

2. Articulation of the Os Calcis with the Cuboid or the Calcaneo-cuboid Articulation (Articulatio Calcaneo-cuboidea) (Fig. 251).

In this joint the articular capsule (capsula articularis) is strengthened at certain points by definite ligaments.

The ligaments connecting the os calcis with the cuboid are four in number:

Dorsal or Superior Calcaneo-cuboid. Two Plantar (Long Calcaneo-cuboid. The Internal Calcaneo-cuboid. Short Calcaneo-cuboid.

The Superior Calcaneo-cuboid Ligament (ligamentum calcaneocuboideum dorsale) (Fig. 252) is a broad portion of the capsule which passes between the contiguous surfaces of the os calcis and cuboid on the dorsal surface of the joint.

The Internal Calcaneo-cuboid or the Interosseous Ligament (pars calcaneo-cuboidea ligamenti bifurcati) is a short but thick and strong band of fibres arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended, at its origin, with the superior calcaneo-scaphoid ligament. These two ligaments are often regarded as a single bifurcated ligament (ligamentum bifurcatum). The internal calcaneo-cuboid ligament is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The Long Calcaneo-cuboid or Long Plantar or Superficial Long Plantar Ligament (ligamentum plantare longum) (Fig. 254), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus: it is attached to the under surface of the os calcis, from near the tuberosities, as far forward as the anterior tubercle; its fibres pass forward to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being continued onward to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

The Short Calcaneo-cuboid or Short Plantar Ligament (ligamentum calcaneocuboideum plantare) (Fig. 254) lies nearer the bones than the preceding, from which it is separated by a little areolar tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle and the depression in front of it, on the forepart of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.

Synovial Membrane (Fig. 255).—The synovial membrane in this joint is distinct. It lines the inner surface of the ligaments.

Actions.—The movements permitted between the os calcis and cuboid are limited to a slight gliding upon each other.

3. The Ligaments Connecting the Os Calcis and Scaphoid or the Calcaneo-scaphoid Articulation Ligaments.

Though these two bones do not directly articulate, they are connected together by two ligaments:

Superior or External Calcaneo-scaphoid. Inferior or Internal Calcaneo-scaphoid.

The Superior or External Calcaneo-scaphoid or Calcaneo-navicular (pars calcaneonavicularis ligamenti bifurcati) arises, as already mentioned, with the internal calcaneo-cuboid in the deep hollow between the astragalus and os calcis,
constituting a part of the ligamentum bifurcatum; it passes forward from the upper surface of the anterior extremity of the os calcis to the outer side of the scaphoid bone. These two ligaments resemble the letter Y, being blended together behind, but separated in front.

The Inferior or Internal Calcaneo-scaphoid or Calcaneo-navicular (ligamentum calcaneonaviculare plantare) (Fig. 254) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, which passes forward and inward from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the scaphoid bone. This ligament not only serves to connect the os calcis and scaphoid, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The upper surface presents a fibro-cartilaginous facet, lined by the synovial membrane continued from the anterior calcaneo-astragaloid articulation, upon which a portion of the head of the astragalus rests. Its under surface is in contact with the tendon of the Tibialis posticus muscle; its inner border is blended with the forepart of the Deltoid ligament, thus completing the socket for the head of the astragalus.

Surgical Anatomy.—The inferior calcaneo-scaphoid ligament, by supporting the head of the astragalus, is principally concerned in maintaining the arch of the foot, and when it yields the head of the astragalus is pressed downward, inward, and forward by the weight of the body, and the foot becomes flattened, expanded, and turned outward, constituting the disease known as flat-foot. This ligament contains a considerable amount of elastic fibre, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the "spring" ligament. It is supported, on its under surface, by the tendon of the Tibialis posticus, which spreads out at its insertion into a number of fasciculi which are attached to most of the tarsal and metatarsal bones; this prevents undue stretching of the ligament and is a protection against the occurrence of flat-foot.

4. Articulation of the Astragalus with the Scaphoid Bone or the Astragalo-scaphoid Articulation (Articulatio Talonavicularis) (Fig. 251).

The articulation between the astragalus and scaphoid is an arthrodial joint: the rounded head of the astragalus being received into the concavity formed by the posterior surface of the scaphoid, the anterior articulating surface of the calcaneum, and the upper surface of the inferior calcaneo-scaphoid ligament, which fills up the triangular interval between these bones. The only ligament of this joint is the superior astragalo-scaphoid (Fig. 249). It is a broad band, which passes obliquely forward from the neck of the astragalus to the superior surface of the scaphoid bone. It is thin, and weak in texture, and covered by the Extensor tendons. The inferior calcaneo-scaphoid ligament supplies the place of an inferior astragalo-scaphoid ligament.

1 Mr. Hancock describes an extension of this ligament upward on the inner side of the foot, which completes the socket of the joint in that direction (Lancet, 1866, vol. i. p. 618).
Synovial Membrane (Fig. 255).—The synovial membrane which lines the joint is continued forward from the anterior calcaneo-astragaloid articulation.

**Actions.**—This articulation permits of considerable mobility, but its feebleness is such as to allow occasionally of dislocation of the other bones of the tarsus from the astragalus.

The transverse tarsal or medio-tarsal joint *(articulatio tarsi transversa [Chopartii])*(Figs. 251 and 256) is formed by the articulation of the os calcis with the cuboid, and by the articulation of the astragalus with the scaphoid. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the sole of the foot may be slightly flexed and extended or carried inward *(inverted)* and outward *(everted)*.

5. **The Articulation of the Scaphoid with the Cuneiform Bones (Articulatio Cuneonavicularis)** (Fig. 251).

The scaphoid is connected to the three cuneiform bones by Dorsal and Plantar ligaments.

The Dorsal Ligaments *(ligamentum navicularicuneiformia dorsalia)* (Figs. 249 and 251) are small, longitudinal bands of fibrous tissue arranged as three bundles, one to each of the cuneiform bones. That bundle of fibres which connects the scaphoid with the internal cuneiform is continued round the inner side of the articulation to be continuous with the plantar ligament which connects these two bones.

The Plantar Ligaments *(ligamentum navicularicuneiformia plantaria)* (Fig. 254) have a similar arrangement to those on the dorsum. They are strengthened by processes given off from the tendon of the Tibialis posticus.

Synovial Membrane (Fig. 255).—The synovial membrane of these joints is part of the great tarsal synovial membrane.

**Actions.**—The movements permitted between the scaphoid and cuneiform bones are limited to a slight gliding upon each other.

6. **The Articulation of the Scaphoid with the Cuboid (Articulatio Cubonavicularis).**

The scaphoid bone is connected with the cuboid by Dorsal, Plantar, and Interosseous ligaments.

The Dorsal Ligament *(ligamentum cuboideonaviculare dorsale)* (Fig. 252) consists of a band of fibrous tissue which passes obliquely forward and outward from the scaphoid to the cuboid bone.

The Plantar Ligament *(ligamentum cuboideonaviculare, plantare)* consists of a band of fibrous tissue which passes nearly transversely between these two bones.

The Interosseous Ligament (Figs. 251 and 255) consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of these two bones.

Synovial Membrane (Fig. 255).—The synovial membrane of this joint is part of the great tarsal synovial membrane.

**Actions.**—The movements permitted between the scaphoid and cuboid bones are limited to a slight gliding upon each other.

7. **The Articulations of the Cuneiform Bones with Each Other or the Intercuneiform Articulations** (Fig. 251).

These bones are connected together by Dorsal, Plantar, and Interosseous ligaments.
The Dorsal Ligaments (ligamenta intercuneiformia dorsalia) consist of two bands of fibrous tissue which pass transversely, one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The Plantar Ligaments (ligamenta intercuneiformia plantaria) have a similar arrangement to those on the dorsum. They are strengthened by the processes given off from the tendon of the Tibialis posticus.

The Interosseous Ligaments (ligamenta intercuneiformia interossea) consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the first and second and the second and third cuneiform bones. The outer portion of the third cuneiform is attached to the cuboid by the ligamentum cuneocuboideum interosseum.

Synovial Membrane (Fig. 255).—The synovial membrane of these joints is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the cuneiform bones are limited to a slight gliding upon each other.

S. The Articulation of the External Cuneiform Bone with the Cuboid (Fig. 251).

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The Dorsal Ligament (ligamentum cuneocuboideum dorsale) (Fig. 252) consists of a band of fibrous tissue which passes transversely between these two bones.

The Plantar Ligament (ligamentum cuneocuboideum plantare) has a similar arrangement. It is strengthened by a process given off from the tendon of the Tibialis posticus.

The Interosseous Ligament (ligamentum cuneocuboideum interosseum) (Fig. 251) consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent sides of these two bones.

Synovial Membrane (Fig. 255).—The synovial membrane of this joint is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the external cuneiform and cuboid are limited to a slight gliding upon each other.

Nerve-supply.—All the joints of the tarsus are supplied by the anterior tibial nerve.

Surgical Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur; though, on account of the spongy character of the bones, they are more frequently broken than dislocated, as the result of violence. When dislocation does occur, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining in situ in the tibio-fibular mortise. This constitutes what is known as the subastragaloid dislocation. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the scaphoid in front—and may even undergo a rotation, either on a vertical or horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upward and downward, so that the trochlear surface faces to one or the other side. Finally, dislocation may occur at the medio-tarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

Pes planus, flat-foot, or splay-foot is a condition in which there is abduction, eversion, and loss of both the longitudinal and the transverse arch. The head of the astragalus passes downward and inward; the anterior portion of the foot is turned outward and the inner side of the foot is lengthened and broadened. Deformity is increased when standing. In severe cases
the patient walks on the inner side of the foot. The condition is due to yielding of the tarsal ligaments. Abduction is permitted by yielding of the internal lateral and calcaneo-astragaloid ligaments. Yielding of the calcaneo-scaphoid ligament permits the head of the astragalus to pass downward and forward, and the entire arch falls. Further deformity is induced by the yielding of the ligaments.

VI. Tarso-metatarsal Articulations (Articulationes Tarsometatarseae [Lisfranci]) (Figs. 249, 251, 252, 254, 257).

These are arthrodial joints. The bones entering into their formation are four tarsal bones—viz., the internal, middle, and external cuneiform and the cuboid—which articulate with the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiform, resting against the middle cuneiform, and being the most strongly articulated of all the metatarsal bones; the third metatarsal articulates with the extremity of the external cuneiform; the fourth, with the cuboid and external cuneiform; and the fifth, with the cuboid. The articular surfaces are covered with cartilage, lined by synovial membrane, and connected together by capsules and by the following ligaments:

Dorsal. Plantar. Interosseous.

The Dorsal Ligaments (ligamenta tarsometatarsea dorsalia) consist of strong, flat, fibrous bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin, fibrous band; the second has three dorsal ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The Plantar Ligaments (ligamenta tarsometatarsea plantaria) consist of longitudinal and oblique fibrous bands connecting the tarsal and metatarsal bones, but disposed with less regularity than on the dorsal surface. Those for the first and second metatarsal are the most strongly marked; the second and third metatarsal receive strong fibrous bands which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsal consist of a few scanty fibres derived from the cuboid.

The Interosseous Ligaments (ligamenta cuneometatarsea interossea) are three in number—internal, middle, and external. The internal one is the strongest of the three, and passes from the outer extremity of the internal cuneiform to the adjacent angle of the second metatarsal. The middle one, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The external interosseous ligament connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

Synovial Membrane (Fig. 255).—The synovial membrane between the internal cuneiform bone and the first metatarsal bone is a distinct sac. The synovial membrane between the middle and external cuneiform behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forward from it—one between the adjacent sides of the second and third metatarsal bones, and one between the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forward between the fourth and fifth metatarsal bones.

Actions.—The movements permitted between the tarsal and metatarsal bones are limited to a slight gliding upon each other.
VII. Articulations of the Metatarsal Bones with Each Other
(Articulations Intermetatarseae) (Figs. 251, 252, 254).

The base of the first metatarsal bone is not connected with the second metatarsal bone by any ligaments; in this respect it resembles the thumb.

The bases of the four outer metatarsal bones are connected together by dorsal, plantar, and interosseous ligaments.

The Dorsal Ligaments (ligamenta basium [oss. metatarsi] dorsalia) consist of bands of fibrous tissue which pass transversely between the adjacent metatarsal bones.

The Plantar Ligaments (ligamenta basium [oss. metatarsi] plantaria) have a similar arrangement to those on the dorsum.

The Interosseous Ligaments (ligamenta basium [oss. metatarsi] interossea) consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces.

Synovial Membrane.—The synovial membrane between the second and third and the third and fourth metatarsal bones is part of the great tarsal synovial membrane. The synovial membrane between the fourth and fifth metatarsal bones is a prolongation of the synovial membrane of the cubo-metatarsal joint (Fig. 255).

Actions.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

The Synovial Membranes in the Tarsal and Metatarsal Joints.

The synovial membranes (Fig. 255) found in the articulations of the tarsus and metatarsus are six in number; one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid and astragalo-scaphoid articulations; a third for the calcaneo-cuboid articulation; and a fourth for the articulations of the scaphoid with the three cuneiform, the three cuneiform with each other, the external cuneiform with the cuboid, and the middle and external cuneiform with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other; a fifth for the internal cuneiform with the metatarsal bone of the great toe; and a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial membrane is sometimes found between the contiguous surfaces of the scaphoid and cuboid bones.
**ARTICULATIONS OF THE PHALANGES**

**Nerve-supply.**—The nerves supplying the tarso-metatarsal joints are derived from the anterior tibial.

The digital extremities of all the metatarsal bones are connected together by the transverse metatarsal ligament.

The Transverse Metatarsal Ligament is a narrow fibrous band which passes transversely across the anterior extremities of all the metatarsal bones, connecting them together. It is blended anteriorly with the plantar (glenoid) ligament of each metatarso-phalangeal articulation. To its posterior border is connected the fascia covering the Interossei muscles. Its inferior surface is concave where the Flexor tendons pass over it. Above it the tendons of the Interossei muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it connects the metatarsal bone of the great toe with the rest of the metatarsal bones.

**VIII. Metatarso-phalangeal Articulations (Articulationes Metatarso-phalangeae).**

The metatarso-phalangeal articulations are of the condyloid kind, formed by the reception of the rounded head of the metatarsal bone into a superficial cavity in the extremity of the first phalanx. Each joint has a capsule and certain other ligaments.

These ligaments are—

- **Plantar.**
- **Two Lateral.**

The Plantar Ligaments or the Glenoid Ligaments of Cruveilhier (ligamenta accessoria plantaria) are thick, dense, fibrous structures. Each is placed on the plantar surface of the joint in the interval between the lateral ligaments, to which it is connected. The plantar ligaments are loosely united to the metatarsal bones, but very firmly to the bases of the first phalanges. The plantar surface of each is intimately blended with the transverse metatarsal ligament, and, except in the great toe, presents a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. The plantar ligament of the great toe contains two large sesamoid bones. By their deep surface they form part of the articular surface for the head of the metatarsal bone, and are lined by synovial membrane.

The Lateral Ligaments (ligamenta collateralia) are strong, rounded cords, placed one on each side of the joint, each being attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone; and, by the other, to the contiguous extremity of the phalanx.

The place of a Posterior Ligament is supplied by the extensor tendon over the back of the joint.

**Actions.**—The movements permitted in the metatarso-phalangeal articulations are flexion, extension, abduction, and adduction.

**IX. Articulations of the Phalanges (Articulationes Digitorum Pedis).**

The articulations of the phalanges are ginglymoid joints. Besides the capsular the ligaments are—

- **Plantar.**
- **Two Lateral (ligamenta collateralia).**

The arrangement of these ligaments is similar to those in the metatarso-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

**Actions.**—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the plantar and lateral ligaments.
Surface Form.—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the medio-tarsal and the tarso-metatarsal. The joint between the astragalus and the scaphoid is best found by means of the tubercle of the scaphoid, for the line of the joint is immediately behind this process. If the foot is grasped and forcibly extended, a rounded prominence, the head of the astragalus, will appear on the inner side of the dorsum in front of the ankle-joint, and if a knife is carried downward, just in front of this prominence and behind the line of the scaphoid tubercle, it will enter the astragalo-scaphoid joint. The calcaneo-cuboid joint is situated midway between the external malleolus and the prominent end of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragalo-scaphoid. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued onward, it would pass through the head of the first metatarsal bone. The joint between the fourth metatarsal bone and the cuboid and external cuneiform is the direct continuation inward of the previous joint, but its plane is less oblique; it would be represented by a line drawn from the outer side of the articulation to the middle of the first metatarsal bone. The plane of the joint between the third metatarsal bone and the external cuneiform is almost transverse. It would be repre-

![Fig. 256.—Line of Chopart's amputation.](Poirier.)

![Fig. 257.—Line of Lisfranc's amputation.](Poirier.)

sented by a line drawn from the outer side of the joint to the base of the first metatarsal bone. The tarso-metatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the scaphoid bone; and the joint between the second metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarso-metatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.

Surgical Anatomy.—Chopart’s amputation passes through the middle tarsal joint (astragalo-scaphoid and calcaneo-cuboid articulation). Fig. 256 shows the line of Chopart. Lisfranc amputated at the tarso-metatarsal articulation. Fig. 257 shows the line of Lisfranc. In Hey’s amputation the fifth, fourth, third, and second metatarsal bones are disarticulated from the tarsus and the internal cuneiform is sawn through. In the operation of Forbes, of Toledo, the cuneiform bones are disarticulated from the scaphoid, the cuboid is sawn through on a line with the surface exposed by the disarticulation.
THE MUSCLES AND FASCIÆ.

MYOLOGY is the branch of anatomy which treats of the muscles. The muscles are formed of bundles of reddish fibres, endowed with the property of contractility. The two principal kinds of muscular tissue found in the body are voluntary and involuntary. The former of these, from the characteristic appearances which its fibres exhibit under the microscope, is known as striated or striped muscle, and from the fact that it is capable of being put into action and controlled by the will, as voluntary muscle. The fibres of the latter do not present any cross-striped appearance, and for the most part are not under the control of the will; hence they are known as unstriated, unstriped, or involuntary muscle. The muscular fibres of the heart differ in certain particulars from both these groups, and they are therefore separately described as cardiac muscular fibres.

Thus it will be seen that there are three varieties of muscular fibres: (1) Transversely striated muscular fibres, which are for the most part voluntary and under the control of the will, but some of which are not so, such as the muscles of the pharynx and upper part of the oesophagus. This variety of muscle is sometimes called skeletal. (2) Transversely striated muscular fibres, which are not under the control of the will—i.e., the cardiac muscles. (3) Plain or unstriated muscular fibres, which are involuntary and controlled by a different part of the nervous system from that which controls the activity of the voluntary muscles. Such are the muscular walls of the stomach and intestine, of the uterus and bladder, of the blood-vessels, etc.

In this section we treat of the skeletal or voluntary muscles only. A muscle is composed of numerous long, narrow muscle cells which shorten when stimulated. The wall of a muscle cell is called the sarcolemma. Muscle cells end either by blending with tendon or aponeurosis or else by rounded or tapering extremities, which are connected to neighboring cells by means of the sarcolemma. Each muscle is composed of bundles or fasciculi of cells or fibres. These bundles are connected together by a connective tissue which is known as the epimysium or external perimysium (perimysium externum), and which is continuous with the sheath of the muscle. Each bundle of muscle fibres is surrounded by the internal perimysium (perimysium internum). The internal perimysium joins the external perimysium externally and the sarcolemma, or tubular sheath, of each fibre internally.

Each muscle cell (fibre) contains numerous nuclei and also fibrillated striated protoplasm. A muscle cell may be 10 cm. in length, and may even extend the entire length of a small muscle (Szymonowicz). The diameter of a cell is from 40μ to 60μ. The striated portion of a cell is differentiated protoplasm, each cell is a portion of unchanged protoplasm (sarcoplasm). In man most muscles are of

1 The Muscles and Fasciae are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciae separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the histology and anatomy of the muscles and fasciae, the special description being given in connection with the different regions.
the red type, but some (mixed muscles) contain red and white fibres. A red muscle fibre contains a considerable quantity of sarcoplasm, and the nuclei are toward the centre of the cell; in a white muscle fibre there is less sarcoplasm, the nuclei are toward the periphery, and striation is very distinct. Striation is due to alteration in the parts of the fibre, so that the altered material has a different refractive index and stains differently from the unaltered portions of the cell.

The Arteries of voluntary muscles pierce the external perimysium and form superficial and deep plexuses that anastomose with each other. These vessels follow the trabeculae between the bundles. Branches enter the bundles and form capillary plexuses, which here and there possess dilatations for the relief of tension during muscular action.

Veins accompany the arteries, and even the smaller ones possess valves (Spalteholz).

The Nerve Endings in voluntary muscle comprise both motor and sensory terminations. A motor nerve pierces the external perimysium and breaks up into numerous branches to form an interfascicular plexus in the internal perimysium. From this plexus nerve fibrils arise and usually one nerve fibril passes to each muscle fibre. The nerve fibril pierces the sarcolemma, the neurilemma and medullary sheath disappearing before the nerve fibril reaches the muscle fibre, and probably being lost by fusing with the sarcolemma. The naked axis-cylinder beneath the sarcolemma of a fibre continues to the surface of the muscle fibre and undergoes arborization to form an end organ. Around the end organ is a quantity of granular sarcoplasm, which, with the nerve end organ, constitutes a sole-plate. A sensory nerve takes origin from a muscle spindle, which consists of a bundle of encapsulated muscle fibre about sensory nerve twigs. From a muscle spindle arise from two to eight large medullated nerve fibres.

The muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they either lie as a flattened layer beneath it, or are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face. The direct continuation of the tendon of a muscle is known as the belly or venter. The origin of a muscle is its head (caput).

The muscles vary extremely in their form. In the limbs they are of considerable length, especially the more superficial ones, the deep ones being generally broad; they surround the bones and form an important protection to the various joints. In the trunk they are broad, flattened, and expanded, forming the parietes of the cavities which they enclose; hence the reason of the terms long, broad, short, etc., used in the description of a muscle.

There is a considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some, the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyro-hyoid. A modification of these is found in the fusiform muscles (m. fusiformis), in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at each end; in their action, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles—e.g., the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line

---

1 A Text-book of Histology. By Dr. Ladislaus Szymonowics. Translated and edited by Dr. John Bruce MacCallum.
of origin intersect at that of their insertion; such is the case in the Pectineus muscle. Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a pen, to one side of a tendon, which runs the entire length of the muscle. Such a muscle is rhomboidal or penniform (m. unipennatus), as the Peronei. A modification of these rhomboidal muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the middle of the muscle; these are called bipenniform (m. bipennatus), and an example is afforded in the Rectus femoris. Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in an orbicular muscle (m. orbicularis) and in that variety of orbicular muscle called a sphincter muscle (m. sphincter). The arrangement of the muscular fibres is of considerable importance in respect to their relative strength and range of movement. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

Muscles differ much in size: the Gastrocnemius forms the chief bulk of the back of the leg, and the fibres of the Sartorius are nearly two feet in length, whilst the Stapedius, a small muscle of the internal ear, weighs about a grain, and its fibres are not more than two lines in length.

The names applied to the various muscles have been derived—1, from their situation, as the Tibialis, Radialis, Ulnaris, Peroneus; 2, from their direction, as the Rectus abdominis, Obliquus capitis, Transversalis; 3, from their uses, as Flexors, Extensors, Abductors, etc.; 4, from their shape, as the Deltoid, Trapezius, Rhomboideus; 5, from the number of their divisions, as the Biceps, the Triceps; 6, from their points of attachment, as the Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid.

In the description of a muscle the term origin is meant to imply its more fixed or central attachment, and the term insertion, the movable point to which the force of the muscle is directed; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face, which are attached by one extremity to the bone and by the other to the movable integument; the greater number of muscles can be made to act from either extremity.

In the dissection of the muscles the student should pay especial attention to the exact origin, insertion, and actions of each, and its more important relations with surrounding parts. An accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their action. By a knowledge of the action of the muscles the surgeon is able to explain the causes of displacement in various forms of fracture and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface-markings they produce, should be especially remembered, as they form useful guides to the surgeon who operates to expose and ligate them.

Tendons.—Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable strength, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior not a trace of them. Nerves also are not present in the smaller tendons, but the larger ones, as the tendo Achillis, receive nerves which accompany nutrient vessels. The tendons consist principally of a substance which yields gelatin.

Aponeuroses.—Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white color, iridescent, glistening, and similar in structure to the tendons.
They are destitute of nerves, and the thicker ones are only sparingly supplied with blood-vessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles, and, on the other hand, with movable structures, as the bones, cartilages, ligaments, fibrous membranes (for instance, the sclerotic). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscular fibre being distinguishable from that of the tendon only by its striation. But where the muscular fibres join the tendon or aponeurosis at an oblique angle the former terminate, according to Kolliker, in rounded extremities, which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

**Fasciae.**—The fasciae (fascia, a bandage) are fibro-areolar or aponeurotic laminae of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. The fasciae have been subdivided, from the situation in which they are found, into two groups, superficial and deep.

**Superficial Fascia** (*panniculus adiposus*).—The superficial fascia is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep or aponeurotic fascia, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. In the eyelids and scrotum, where adipose tissue is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body; in the groin it is so thick as to be capable of being subdivided in several laminae. Beneath the fatty layer of the superficial fascia, which is immediately subcutaneous, there is generally another layer of the same structure, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as the superficial epigastric vessels in the abdominal region, the radial and ulnar veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymphatic glands; certain cutaneous muscles also are situated in the superficial fascia, as the Platysma myoides in the neck, and the Orbicularis palpebrarum around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perineum, and extremities; is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands and soles of the feet, forming a fibro-fatty layer which binds the integument firmly to the subjacent structure. The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft medium for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolae is a bad conductor of heat.

**Deep Fascia.**—The deep or aponeurotic fascia is a dense, inelastic, unyielding fibrous membrane, forming sheaths for the muscles and affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It is usually exposed on the removal of the superficial fascia, forming a strong investment, which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciae are thick in unprotected situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciae assist the muscles in their action by the degree of tension and pressure they make upon their surface; and in certain situations this is increased and regulated by muscular action; as, for instance, by
the Tensor fasciae femoris and Gluteus maximus in the thigh, by the Biceps in the upper and lower extremities, and Palmaris longus in the hand. In the limbs the fasciae not only invest the entire limb, but give off septa which separate the various muscles, and are attached beneath to the periosteum: these prolongations of fasciae are usually spoken of as intermuscular septa.

The Muscles and Fasciae may be arranged, according to the general division of the body, into those of the cranium, face, and neck; those of the trunk; those of the upper extremity; and those of the lower extremity.

**MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE.**

The muscles of the cranium and face consist of ten groups, arranged according to the region in which they are situated:

1. Cranial Region.
   Occipito-frontalis.

2. Auricular Region.
   Attrahens auriculam.
   Attollens auriculam.
   Retrahens auriculam.

3. Palpebral Region.
   Orbicularis palpebrarum.
   Corrugator superciliii.
   Tensor tarsi.

4. Orbital Region.
   Levator palpebræ.
   Rectus superior.
   Rectus inferior.
   Rectus internus.
   Rectus externus.
   Obliquus superior.
   Obliquus inferior.

5. Nasal Region.
   Pyramidalis nasi.
   Levator labii superioris alæque nasi.
   Dilatator naris posterior.
   Dilatator naris anterior.
   Compressor nasi.
   Compressor narium minor.
   Depressor alæ nasi.

6. Maxillary Region.
   Levator labii superioris.
   Levator anguli oris.
   Zygomaticus major.
   Zygomaticus minor.

7. Mandibular Region.
   Levator labii inferioris.
   Depressor labii inferioris.
   Depressor anguli oris.

8. Internamillary Region.
   Buccinato.
   Risorius.
   Orbicularis oris.

9. Temporo-mandibular Region.
   Masseter.
   Temporal.

10. Pterygo-mandibular Region.
    Pterygoideus externus.
    Pterygoideus internus.
1. The Cranial Region.

Occipito-frontalis.

Dissection (Fig. 258).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin from before backward, commencing at the root of the nose in front, and terminating behind at the occipital protuberance; make a second incision in a horizontal direction along the forehead and round the side of the head, from the anterior to the posterior extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upward; this must be done with extreme care, removing the integument from the outer surface of the vessels and the nerves which lie immediately beneath the skin.

The Skin of the Scalp.—This is thicker than in any other part of the body. It is intimately adherent to the superficial fascia, which attaches it firmly to the underlying aponeurosis and muscle. Movements of the muscle move the skin. The hair-follicles are very closely set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

Superficial Fascia.—The superficial fascia in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the occipito-frontalis and its tendinous aponeurosis; it is continuous, behind, with the super-
ficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

**Surgical Anatomy.**—The subcutaneous tissue is composed of bands of fibrous tissue enclosing spaces filled with fat. The fibrous character of this tissue greatly limits discoloration and swelling when inflammation occurs. The edges of a wound which does not involve the aponeurosis or muscle do not retract, hence the wound does not gap. The blood-vessels run practically in the skin, and as they lie in very dense tissue and are adherent to it, wounds bleed profusely, the arteries being unable to freely contract and retract. It is very difficult or impossible to pick up with forceps a vessel in the skin of the scalp, and bleeding must be arrested by suture ligatures or by the stitches which close the wound. Sebaceous glands in the skin of the scalp may develop into sebaceous cysts (wens).

**The Occipito-frontalis (m. epicranius) (Fig. 260).**—The Occipito-frontalis is a broad musculo-fibrous layer, which covers the whole of one side of the
vertex of the skull, from the occiput to the eyebrow. It consists of two muscular slips, separated by an intervening tendinous aponeurosis. The occipital portion, the occipitalis muscle (m. occipitalis), is thin, quadrilateral in form, and about an inch and a half in length; it arises from the outer two-thirds of the superior curved line of the occipital bone, and from the mastoid portion of the temporal bone. Its fibres of origin are tendinous, but they soon become muscular, and ascend in a parallel direction to terminate in a tendinous aponeurosis. The frontal portion, the frontalis muscle (m. frontalis), is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader, its fibres are longer, and their structure paler than the occipital portion. Its internal fibres are continuous with those of the Pyramidalis nasi. Some anatomists consider the Pyramidalis muscle as simply the lower fibres of the frontalis, and give these bundles of muscle fibre the name of musculus procerus. Its middle fibres become blended with the Corrugator supercili and Orbicularis palpebrarum; and the outer fibres are also blended with the latter muscle over the external angular process. According to Theile, the innermost fibres are attached to the nasal bones, the outer to the external angular process of the frontal bone. From these attachments the fibres are directed upward, and join the aponeurosis below the coronal suture. The inner margins of the frontal portions of the two muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The middle portion of the Occipito-frontalis muscle or the aponeurosis (epiantral aponeurosis, Galea aponeurotica) covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. Behind, it is attached, in the interval between the occipital origins, to the occipital protuberance and highest curved lines of the occipital bone; in front, it forms a short and narrow prolongation between the frontal portions; and on each side it has connected with it the Attollens and Aurahenus auriculac muscules. This aponeurosis is closely connected to the integument by the firm, dense, fibro-fatty layer which forms the superficial fascia; it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the integument. It is continuous with the temporal fascia below the temporal ridge, and it is in reality the representative of the deep fascia.

Nerves.—The frontal portion of the Occipito-frontalis is supplied by the facial nerve; its occipital portion by the posterior auricular branch of the facial.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forward, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backward. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forward and backward. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise: if the action is more exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

Surgical Anatomy.—The skull is covered by the scalp (Fig. 259). This consists of five layers: (1) the pericranium; (2) a layer of connective tissue beneath the Occipito-frontalis aponeurosis (subaponeurotic tissue); (3) the Occipito-frontalis muscle and aponeurosis; (4) subcutaneous fat; (5) skin. If a wound involves the muscle or aponeurosis, it gaps widely, the greatest amount of gaping being observed in transverse wounds. The space between the aponeurosis and the pericranium is called by Treves the dangerous area of the scalp. It contains a layer of connective tissue and suppuration in this tissue spreads widely. An abscess in the dangerous area
should be opened above the superior curved line of the occipital bone, above the eyebrow or above the zygoma. In a wound or contusion above the aponeurosis but little blood can be, effused in the tissue because the fibrous structure prevents it, and abscesses do not tend to spread widely. Between the aponeurosis and the pericranium a great amount of blood can be effused. An effusion of blood beneath the pericranium is called a cephalhæmatoma. Such a condition may occur from pressure during birth. An extravasation beneath the pericranium is limited to the surface of one bone. The pericranium is tightly attached to the sutures, but adheres lightly to the surface of the bone, and abscess beneath the pericranium is restricted to the surface of one bone.

2. The Auricular Region (Fig. 260).

Attrahens auriculam.

Retrahens auriculam.

Attollens auriculam.

These three small muscles are placed immediately beneath the skin around the external ear. In man, in whom the external ear is almost immovable, they are rudimentary. They are the analogues of large and important muscles in some of the mammalia.

Dissection.—This requires considerable care, and should be performed in the following manner: To expose the Attollens auriculam, draw the pinna, or broad part of the ear, downward, when a tense band will be felt beneath the skin, passing from the side of the head to the upper part of the concha; by dividing the skin over this band in a direction from below upward, and then reflecting it on each side, the muscle is exposed. To bring into view the Attrahens auriculam, draw the helix backward by means of a hook, when the muscle will be made tense, and may be exposed in a similar manner to the preceding. To expose the Retrahens auriculam, draw the pinna forward, when the muscle, being made tense, may be felt beneath the skin at its insertion into the back part of the concha, and may be exposed in the same manner as the other muscles.

The Attrahens Auriculam or Aurem (m. auricularis anterior), the smallest of the three, is thin, fan-shaped, and its fibres pale and indistinct; they arise from the lateral edge of the aponeurosis of the Occipito-frontalis, and converge to be inserted into a projection on the front of the helix.

Relations.—Superficially, with the skin; deeply, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which are the temporal artery and vein and the temporal fascia.

The Attollens Auriculam or Aurem (m. auricularis superior), the largest of the three, is thin and fan-shaped: its fibres arise from the aponeurosis of the Occipito-frontalis and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

Relations.—Superficially, with the integument; deeply, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which is the temporal fascia.

The Retrahens Auriculam or Aurem (m. auricularis posterior) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Relations.—Superficially, with the integument; deeply, with the mastoid portion of the temporal bone and the posterior auricular artery and nerve.

Nerves.—The Attrahens and Attollens auriculam are supplied by the temporal branch of the facial; the Retrahens auriculam is supplied by the posterior auricular branch of the same nerve.

Actions.—In man, these muscles possess very little action: the Attrahens auriculam draws the ear forward and upward; the Attollens auriculam slightly raises it; and the Retrahens auriculam draws it backward.
3. The Palpebral Region (Fig. 260).

Orbicularis palpebrarum.  Levator palpebræ.
Corrugator supercili.  Tensor tarsi.

Dissection (Fig. 257).—In order to expose the muscles of the face, continue the longitudinal incision made in the dissection of the Occipito-frontalis down the median line of the face to the tip of the nose, and from this point onward to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the jaw. Then make an incision in front of the external ear, from the angle of the jaw upward, to join the transverse incision made in exposing the Occipito-frontalis. These incisions include a square-shaped flap, which should be removed in the direction marked in the figure, with care, as the muscles at some points are intimately adherent to the integument.

The Orbicularis Palpebrarum (m. orbicularis oculi) is a sphincter muscle, which surrounds the circumference of the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the nasal process of the superior maxillary bone in front of the lacrimal groove for the nasal duct, and from the anterior surface and borders of a short tendon, the tendo oculi, or internal tarsal ligament, placed at the inner angle of the orbit. From this origin the fibres are directed outward, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple and downward on the cheek. The internal or palpebral portion (pars palpebralis) of the Orbicularis is thin and pale; it arises from the bifurcation of the tendo palpebrarum, and forms a series of concentric curves, which are on the outer side of the eyelids inserted into the external tarsal ligament. The external or orbital portion (pars orbitalis) is thicker and of a reddish color: its fibres are well developed, and form complete ellipses. The upper fibres of this portion blend with the Occipito-frontalis and Corrugator supercili. 

Relations.—By its superficial surface, with the integument. By its deep surface, above, with the Occipito-frontalis and Corrugator supercili, with which it is intimately blended, and with the supraorbital vessels and nerve; below, it covers the lacrimal sac, and the origin of the Levator labii superioris alaeque nasi, the Levator labii superioris, and the Zygomaticus minor muscles. Internally, it is occasionally blended with the Pyramidalis nasi. Externally, it lies on the temporal fascia. On the eyelids it is separated from the conjunctiva by the Levator palpebræ, the tarsal ligaments, the tarsal plates, and the Meibomian glands.

The tendo oculi or internal tarsal ligament (ligamentum palpebrale mediale) is a short tendon, about two lines in length and one in breadth, attached to the nasal process of the superior maxillary bone in front of the lacrimal groove. Crossing the lacrimal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lacrimal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lacrimal bone. This is the reflected aponeurosis of the tendo oculi.

The external tarsal ligament (raphe palpebralis lateralis) is a much weaker structure than the tendo oculi. It is attached to the margin of the frontal process of the malar bone, and passes inward to the outer commissure of the eyelids; it connects together the outer extremities of the two tarsal cartilages.

Use of Tendo Oculi.—Besides giving attachment to part of the Orbicularis palpebrarum and to the tarsal plates, it serves to suck the tears into the lacrimal sac, by its attachment to the sac. Thus, each time the eyelids are closed, the tendo oculi becomes tightened, through the action of the Orbicularis, and draws the wall of the lacrimal sac outward and forward, so that a vacuum is made in the sac, and the tears are sucked along the lacrimal canals into it.
The Corrugator Supercilii (Figs. 259 and 260) is a small narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipito-frontalis and Orbicularis palpebrarum muscles. It arises from the inner extremity of the superciliary ridge, from whence its fibres pass upward and outward, and are inserted into the deep surface of the skin, opposite the middle of the orbital arch.

Relations.—By its anterior surface with the Occipito-frontalis and Orbicularis palpebrarum muscles; by its posterior surface, with the frontal bone and supra trochlear nerve.

The Levator Palpebræ will be described with the muscles of the orbital region.

The Tensor Tarsi or Horner's Muscle (pars lacrimalis of the orbicularis palpebrarum) (Fig. 261) is a small thin muscle about three lines in breadth and six in length, situated at the inner side of the orbit, behind the tendo oculi. It is usually considered to be composed of fibres derived from the Orbicularis palpebrarum. It arises from the crest and adjacent part of the orbital surface of the lachrymal bone, and, passing across the lachrymal sac, divides into two slips, which cover the lachrymal canals and are inserted into the tarsal plates internal to the puncta lachrymalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum; it is occasionally very indistinct.

Nerves.—The Orbicularis palpebrarum, Corrugator supercili, and Tensor tarsi are supplied by the facial nerve. Recent investigations tend to show that the Orbicularis palpebrarum, Corrugator supercili, and frontal part of the Occipito-frontalis are in reality supplied by fibres of the third nerve, which descend through the pons varolii to join the facial nerve.

Actions.—The Orbicularis palpebrarum is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inward toward the inner angle of the orbit, and the eyelids are firmly closed as in photo-
phobia. When the skin of the forehead, temple, and cheek is thus drawn inward by the action of the muscle it is thrown into folds, especially radiating from the outer angle of the eyelids, which give rise in old age to the so-called "crow's feet." The Levator palpebre is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe. The Corrugator supercilii draws the eyebrow downward and inward, producing the vertical wrinkles of the forehead. It is the "frowning" muscle, and may be regarded as the principal agent in the expression of suffering. The Tensor tarsi draws the eyelids inward and compresses the eyelids and the extremities of the lachrymal canals against the surface of the globe of the eye; thus placing the canals in the most favorable situation for receiving the tears. It serves, also, to compress the lachrymal sac.  

4. The Orbital Region (Fig. 262).

Levator palpebre superioris. Rectus internus.
Rectus superior. Rectus externus.
Rectus inferior. Obliquus oculi superior.

Obliquus oculi inferior.

Dissection.—To open the cavity of the orbit, remove the skull-cap and brain; then saw through the frontal bone at the inner extremity of the supraorbital ridge, and externally at its junction with the malar. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the Obliquus superior. When the fragments are cleared away, the peristium of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onward into the globe; insert the point of a blowpipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature round the nerve so as to prevent the air escaping. The globe being now drawn forward, the muscles will be put upon the stretch.

The Levator Palpebreæ Superioris is thin, flat, and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Superior rectus (Fig. 263). At its origin it is narrow and tendinous, but soon becomes broad and fleshy, and finally terminates in a wide aponeurosis, which is inserted into the upper margin of the superior tarsal plate. From this aponeurosis a thin expansion is continued onward, passing between the fibres of the Orbicularis
to be inserted into the skin of the lid, and some deeper fibres blend with an expansion from the sheath of the Superior rectus muscle, and are with it prolonged into the conjunctiva.

Relations.—By its upper surface, with the frontal nerve and supraorbital artery, the periosteum of the orbit and lachrymal gland; and, in the lid, with the inner surface of the tarsal ligament; by its under surface, with the Superior rectus, and, in the lid, with the conjunctiva. A small branch of the third nerve enters its under surface.

The Superior Rectus (m. rectus superior), the thinnest and narrowest of the four Recti, arises from the upper margin of the optic foramen (Fig. 263) beneath the Levator palpebrae, and from the fibrous sheath of the optic nerve; and is inserted by a tendinous expansion into the sclerotic coat, about three or four lines from the margin of the cornea.

Relations.—By its upper surface, with the Levator palpebrae; by its under surface, with the optic nerve, the ophthalmic artery, the nasal nerve, and the branch of the third nerve which supplies it; and, in front, with the tendon of the Superior oblique and the globe of the eye.

The Inferior Rectus (m. rectus inferior) and the Internal Rectus (m. rectus medialis) arise by a common tendon, the ligament of Zinn1 (annulus tendineus communis), which is attached round the circumference of the optic foramen, except at its upper and outer part (Fig. 263).

The External Rectus (m. rectus lateralis) has two heads: the upper one arises from the outer margin of the optic foramen immediately beneath the Superior rectus; the lower head, partly from the ligament of Zinn and partly from a small pointed process of bone on the lower margin of the sphenoidal fissure (Fig. 263). Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion, the tunica albuginea, into the sclerotic coat, about three or four lines from the margin of the cornea. Between the two heads of the External rectus is a narrow interval, through which passes the third, the nasal branch of the ophthalmic division of the fifth and sixth nerves, and the ophthalmic vein. Although nearly all of these muscles present a common origin and are inserted in a similar manner into the sclerotic coat, there are certain differences to be observed in them as regards their length and breadth. The Internal rectus is the broadest, the External is the longest, and the Superior is the thinnest and narrowest.

The Superior Oblique (m. obliquus superior) is a fusiform muscle placed at the upper and inner side of the orbit, internal to the Levator palpebrae. It arises about a line above the inner margin of the optic foramen (Fig. 263), and, passing forward to the inner angle of the orbit, terminates in a rounded tendon, which plays in a ring or pulley, the trochlea (trochlea m. obliqui superioris), formed by a cartilaginous tissue attached to a depression beneath the internal angular process of the frontal bone, the contiguous surfaces of the tendon and ring being lined by a delicate synovial membrane and enclosed in a thin fibrous investment. The tendon is reflected backward, outward, and downward beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into

1 The ligament of Zinn ought, perhaps more appropriately, to be termed the opennurcina or tendon of Zinn, Mr. C. B. Lockwood has described a somewhat similar structure on the under surface of the Superior rectus muscle, which is attached to the lesser wing of the sphenoid, forming the upper and outer margin of the optic foramen. This superior tendon gives origin to the Rectus superior, the superior head of the External rectus, and the upper part of the Internal rectus.—Journal of Anatomy and Physiology, vol. xx. part 1, p. 1.
the sclerotic coat, behind the equator of the eyeball, the insertion of the muscle lying between the Superior and External recti.

Relations.—By its upper surface, with the periosteum covering the roof of the orbit and the fourth nerve: the tendon, where it lies on the globe of the eye, is covered by the Superior rectus; by its under surface, with the nasal nerve, ethmoidal arteries, and the upper border of the internal rectus.

The Inferior Oblique (m. obliquus inferior) is a thin, narrow muscle placed near the anterior margin of the orbit. It arises from a depression on the orbital plate of the superior maxillary bone, external to the lachrymal groove (Fig. 262). Passing outward, backward, and upward between the Inferior rectus and the floor of the orbit, and then between the eyeball and the External rectus, it is inserted into the outer part of the sclerotic coat between the Superior and External recti, near to, but somewhat behind, the tendon of insertion of the Superior oblique.

Relations.—By its ocular surface, with the globe of the eye and with the Inferior rectus; by its orbital surface, with the periosteum covering the floor of the orbit, and with the External rectus. Its borders look forward and backward; the posterior one receives a branch of the third nerve.

The orbital muscle or Müller’s muscle (musculus orbitalis), which spans the sphen-maxillary fissure and infraorbital groove, is composed of non-striated fibres, and is a rudimentary structure continuous with the periosteum of the orbit.¹

Nerves.—The Levator palpebrae, Inferior oblique, and all the Recti excepting the External, are supplied by the third nerve; the Superior oblique, by the fourth; the External rectus, by the sixth.

Actions.—The Levator palpebrae raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti muscles are attached in such a manner to the globe of the eye that, acting singly, they will turn it either upward, downward, inward, or outward, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for, inasmuch as they pass obliquely outward and forward to the eyeball, the elevation or depression of the cornea must be accompanied by a certain deviation inward, with a slight amount of rotation, which, however, is corrected by the Oblique muscles, the Inferior oblique correcting the deviation inward of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External and Internal recti, on the other hand, produces a purely horizontal movement. If any two contiguous recti of one eye act together, they carry the globe of the eye in the diagonal of these directions—viz., upward and inward, upward and outward, downward and inward, or downward and outward. The movement of circumduction, as in looking round a room, is performed by the alternate action of the four Recti. The Oblique muscles rotate the eyeball on its antero-posterior axis, this kind of movement being required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of each eye.² It should be noted that sometimes the corresponding Recti and sometimes the opposite ones of the two eyes act together; for instance, the two superior and inferior Recti carry both eyeballs upward and downward, respectively. In looking toward the right the right External and left Internal recti act together, the reverse being the case in looking toward the left. In turning both eyes toward the middle line, as in directing our vision toward an object less than twenty feet distant, the two internal recti act together.

Fascie of the Orbit.—The connective tissue of the orbit is in various places condensed into thin membranous layers, which may be conveniently described as

¹ See F. Gropper, in the Vienna Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften, 1903, Band cxii.
² On the Oblique Muscles of the Eye in Man and Vertebrate Animals, by John Struthers, M.D., in Anatomical and Physiological Observations. For a fuller account of the various co-ordinate actions of the muscles of a single eye and of both eyes than our space allows see Dr. M. Foster's Text-book of Physiology.
(1) the orbital fascia; (2) the sheaths of the muscles; and (3) the covering of the eyeball.

(1) The Orbital Fascia.—This forms the periosteum of the orbit. It is loosely connected to the bones, from which it can be readily separated. Behind, it is connected with the dura mater by processes which pass through the optic foramen and sphenoidal fissure, and with the sheath of the optic nerve. In front it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the palpebral fascia. From its internal surface two processes are given off—one to enclose the lacrimal gland, the other to hold the pulley of the Superior oblique muscle in position.

(2) The Sheaths of the Muscles.—The sheaths of the muscles give off expansions to the margins of the orbit which limit the action of the muscles.

(3) The Covering of the Eyeball—Ténon’s capsule—surrounds the posterior two-thirds of the eyeball; it will be described in the sequel.

Surgical Anatomy.—The position and exact point of insertion of the tendons of the Internal and External recti muscles into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide the one or the other muscle for the cure of strabismus (squint). In convergent strabismus, which is the more common form of the disease, the eye is turned inward, requiring the division of the Internal rectus. In the divergent form, which is more rare, the eye is turned outward, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: The lids are to be well separated; the eyeball being rotated outward or inward, the conjunctiva should be raised by a pair of forceps and divided immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclerotic; the submucous areolar tissue is then divided, and into the small aperture thus made a blunt hook is passed upward between the muscle and the globe, and the tendon of the muscle and conjunctiva covering it divided by a pair of blunt-pointed scissors. Or the tendon may be divided by a subconjunctival incision, one blade of the scissors being passed upward between the tendon and the conjunctiva, and the other between the tendon and the sclerotic. The student, when dissecting these muscles, should remove on one side of the subject the conjunctiva from the front of the eye, in order to see more accurately the position of the tendons, while on the opposite side the operation may be performed. Inflammation of the synovial membrane lining the trochlea of the Superior oblique may lead to the formation of a cyst of considerable size.

In performing enucleation of the eyeball the conjunctiva is clipped with scissors near the cornea and the capsule of Ténon is divided with it. One rectus muscle after another is caught up on a blunt hook and divided. The scissors are now pushed well in along the outer orbital wall and the optic nerve is divided. Finally the oblique muscles, the ciliary vessels and nerves, and fragments of tissue helping to retain the globe are cut and the eyeball is enucleated.

An orbital abscess is evacuated by making an incision close to the border of the orbit, above or below the eyeball.

5. The Nasal Region (Fig. 260).

Pyramidalis nasi. Dilatator naris anterior.

Levator labii superioris alæque nasi. Compressor nasi.

Dilatator naris posterior. Compressor narium minor.

Depressor alæ nasi.

The Pyramidalis Nasi is a small pyramidal slip placed over the nasal bone. Its origin is by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the cartilage, where it blends with the Compressor nasi, and it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Occipito-frontalis (see page 368).

Relations.—By its upper surface, with the skin; by its under surface, with the frontal and nasal bones.

The Levator Labii Superioris Alæque Nasi is a thin triangular muscle placed by the side of the nose, and extending between the inner margin of the orbit and
upper lip. It arises by a pointed extremity from the upper part of the nasal process of the superior maxillary bone, and, passing obliquely downward and outward, divides into two slips, one of which is inserted into the cartilage of the ala of the nose and the under surface of the skin over the ala; the other is prolonged into the upper lip, becoming attached to the under surface of the skin and blended with the Orbicularis oris and Levator labii superioris proprius.

Relations.—In front, with the integument, and with a small part of the Orbicularis palpebrarum above.

The Dilatator Naris Posterior is a small muscle which is placed partly beneath the elevator of the nose and lip. It arises from the margin of the nasal notch of the superior maxilla and from the sesamoid cartilages, and is inserted into the skin near the margin of the nostril.

The Dilatator Naris Anterior is a thin delicate fasciculus passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The Compressor Nasi is a small, thin, triangular muscle arising by its apex from the superior maxillary bone, above and a little external to the incisive fossa; its fibres proceed upward and inward, expanding into a thin aponeurosis which is attached to the fibro-cartilage of the nose and is continuous on the bridge of the nose with that of the muscle of the opposite side and with the aponeurosis of the Pyramidalis nasi. His uses the term musculus nasalis to include the Compressor nasi (transverse portion of the nasal muscle), and the Dilatator naris posterior and the Dilatator naris anterior (alar portion of the nasal muscle).

The Compressor Narium Minor is a small muscle attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The Depressor Alae Nasi (depressor septi) is a short radiated muscle arising from the incisive fossa of the superior maxilla; its fibres ascend to be inserted into the septum and back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

Nerves.—All of the muscles of this group are supplied by the facial nerve.

Actions.—The Pyramidalis nasi draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The Levator labii superioris alaeque nasi draws upward the upper lip and ala of the nose; its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two Dilatatores nasi enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing they may be noticed to be in violent action, as well as in some emotions, as anger. The Depressor alae nasi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downward, and thereby constricting the aperture of the nares. The Compressor nasi depresses the cartilaginous part of the nose and compresses the alae together.

6. The Superior Maxillary Region (Fig. 260).

| Levator labii superioris. | Zygomaticus major. |
| Levator anguli oris. | Zygomaticus minor. |

By the term musculus quadratus labii superioris, His includes three muscles. The caput angulare is called in this book the Levator labii superioris alaeque nasi. The caput infraorbitale is called the Levator labii superioris. The caput zygomaticum is called the Zygomaticus minor.

The Levator Labii Superioris (proprius) is a thin muscle of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infra-
orbital foramen, some of its fibres being attached to the superior maxilla, others to the malar bone; its fibres converge to be inserted into the muscular substance of the upper lip.

Relations.—By its superficial surface above, with the lower segment of the Orbicularis palpebrarum; below, it is subcutaneous. By its deep surface it conceals the origin of the Compressor nasi and Levator anguli oris muscles, and the infraorbital vessels and nerve, as they escape from the infraorbital foramen.

The **Levator Anguli Oris** (m. caninus) arises from the canine fossa immediately below the infraorbital foramen; its fibres incline downward and a little outward, to be inserted into the deep surface of the skin and into the subcutaneous tissue near the angle of the mouth and intermingles with the fibres of the Zygomaticus major, the Depressor anguli oris, and the Orbicularis.

Relations.—By its superficial surface, with the Levator labii superioris and the infraorbital vessels and nerves; by its deep surface, with the superior maxilla, the Buccinator, and the mucous membrane.

The **Zygomaticus Major** (m. zygomaticus) is a slender fasciculus which arises from the malar bone, in front of the zygomatic suture, and, descending obliquely downward and inward, is inserted into the deep surface of the skin and subcutaneous tissue at the outer portion of the upper lip and into the angle of the mouth, where it blends with the fibres of the Levator anguli oris, the Orbicularis oris, and the Depressor anguli oris.

Relations.—By its superficial surface, with the subcutaneous adipose tissue; by its deep surface, with the Masseter and Buccinator muscles and the facial artery and vein.

The **Zygomaticus Minor**, which is often absent, arises from the malar bone immediately behind the maxillary suture, and, passing downward and inward, is inserted into the deep surface of the skin and the adjacent muscles at the upper margin of the exposed vermillion surface of the lip midway between the middle line of the lip and the angle of the mouth. It is continuous with the Orbicularis oris at the outer margin of the Levator labii superioris. It lies in front of the preceding.

Relations.—By its superficial surface, with the integument and the Orbicularis palpebrarum above; by its deep surface, with the Masseter, Buccinator, and Levator anguli oris, and the facial artery and vein.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii superioris is the proper elevator of the upper lip, carrying it at the same time a little forward. It assists in forming the naso-labial ridge, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The Levator anguli oris raises the angle of the mouth and draws it inward, and assists the Levator labii superioris in producing the naso-labial ridge. The Zygomaticus major draws the angle of the mouth backward and upward, as in laughing; whilst the Zygomaticus minor, being inserted into the outer part of the upper lip and not into the angle of the mouth, draws it backward, upward, and outward, and thus gives to the face an expression of sadness.

7. The Mandibular Region (Fig. 260).

**Levator labii inferioris.**  **Depressor labii inferioris.**  **Depressor anguli oris.**

Dissection.—The muscles in this region may be dissected by making a vertical incision through the integument from the margin of the lower lip to the chin; a second incision should then be carried along the margin of the lower jaw as far as the angle, and the integument carefully removed in the direction shown in Fig. 258.
The **Levator Labii Inferioris** or **Levator Menti** (*m. mentalis*) is to be dissected by everting the lower lip and raising the mucous membrane. It is a small conical fasciculus placed on the side of the frenum of the lower lip. It *arises* from the incisive fossa, external to the symphysis of the lower jaw; its fibres descend to be inserted into the integument of the chin.

**Relation.**—On its *inner surface*, with the mucous membrane; in the *median line*, it is blended with the muscle of the opposite side; and on its *outer side*, with the Depressor labii inferioris.

The **Depressor Labii Inferioris** or **Quadratus Menti** (*m. quadratus labii inferioris*) (Fig. 264) is a small quadrilateral muscle. It *arises* from the external oblique line of the lower jaw, between the symphysis and mental foramen, and passes obliquely upward and inward, to be inserted into the integument of the lower lip, its fibres blending with the Orbicularis oris and with those of its fellow of the opposite side. It is continuous with the fibres of the Platysma at its origin. This muscle contains much yellow fat intermingled with its fibres.

**Relations.**—By its *superficial surface*, with part of the Depressor anguli oris and with the integument, to which it is closely connected; by its *deep surface*, with the mental vessels and nerves, the mucous membrane of the lower lip, the labial glands, and the Levator menti, with which it is intimately united.

The **Depressor Anguli Oris** or **Triangularis Menti** (*m. triangularis*) (Fig. 260) is triangular in shape, *arising*, by its broad base, from the external oblique line of the lower jaw, from whence its fibres pass upward, to be *inserted*, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris. Muscular fibres connecting the two muscles below the chin are occasionally met with; they constitute the **Musculus transversus menti** of His and Waldeyer.

**Relations.**—By its *superficial surface*, with the integument; by its *deep surface*, with the Depressor labii inferioris and Buccinator.

**Nerves.**—This group of muscles is supplied by the facial nerve.

**Actions.**—The Levator labii inferioris raises the lower lip and protrudes it forward, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downward and a little outward, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist to the Levator anguli oris and Zygomaticus major; acting with these muscles, it will draw the angle of the mouth directly backward.

### 8. The Intermaxillary Region.

**Orbicularis oris.**  
**Buccinator.**  
**Risorius.**

**Dissection.**—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches and the integument carefully removed from the surface.

The **Orbicularis oris** (Figs. 260 and 264) is not a sphincter muscle, like the Orbicularis palpebrarum, but consists of numerous strata of muscular fibres, having different directions, which surround the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of them—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the upper jaw passing to the lower lip, and those from the lower jaw to the upper lip. Other fibres of the muscle, situated at
its upper and lower part, pass across the lips from side to side without decussation. Superficial to this stratum is a second, formed by the Levator and Depressor anguli oris, which cross each other at the angle of the mouth, those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addi-

Fig. 264.—Temporal and deep muscles about the mouth. (Testut.)

tion to these there are fibres from the other muscles inserted into the lips—the Levator labii superioris, the Levator labii superioris alaeque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane through the thickness of the lip. And in addition to these are fibres
by which the muscle is connected directly with the maxillary bones and the septum of the nose. These consist, in the upper lip, of four bands, two of which (m. incisivus superior) arise from the alveolar border of the superior maxilla, opposite the lateral incisor tooth, and, arching outward on each side, are continuous at the angles of the mouth with the other muscles inserted into this part. The two remaining muscular slips, called the Nasolabialis, connect the upper lip to the back of the septum of the nose: as they descend from the septum an interval is left between them. It is this interval which forms the depression seen on the surface of the skin beneath the septum of the nose, which is called the philtrum. The additional fibres for the lower segment (m. incisivus inferior) arise from the inferior maxilla, externally to the Levator labii inferioris, and arch outward to the angles of the mouth, to join the Buccinator and the other muscles attached to this part.

Relations.—By its superficial surface, with the integument, to which it is closely connected; by its deep surface, with the buccal mucous membrane, the labial glands, and coronary vessels; by its outer circumference it is blended with the numerous muscles which converge to the mouth from various parts of the face. Its inner circumference is free, and covered by the mucous membrane.

The Buccinator (Fig. 264) is a broad, thin muscle, quadrilateral in form, which occupies the interval between the jaws at the side of the face. It arises from the outer surface of the alveolar processes of the upper and lower jaws, corresponding to the three molar teeth, and, behind, from the anterior border of the pterygo-maxillary ligament. The fibres converge toward the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the inferior segment; the highest and lowest fibres continue forward uninterrupted into the corresponding segment of the lip, without decussation.

Relations.—By its superficial surface, behind, with a large mass of fat, the sucking or suctorial pad (corpus adiposum buccae), which separates it from the ramus of the lower jaw, the Masseter, and a small portion of the Temporal muscle. The sucking pad is much more developed relatively in children than in adults. It assists sucking by aiding the cheek to resist atmospheric pressure. The buccinator muscle is in relation, anteriorly, with the Zygomatici, Risorius, Levator anguli oris, Depressor anguli oris, and Stenson's duct, which pierces it opposite the second molar tooth of the upper jaw; the facial artery and vein cross it from below upward; it is also crossed by the branches of the facial and buccal nerves; by its internal surface, with the buccal glands and mucous membrane of the mouth.

The Pterygo-maxillary or Pterygo-mandibular Ligament (raphe pterygomandibularis) separates the Buccinator muscle from the Superior constrictor of the pharynx. It is a tendinous thickening of the bucco-pharyngeal fascia, attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the internal oblique line of the lower jaw. Its inner surface corresponds to the cavity of the mouth, and is lined by mucous membrane. Its outer surface is separated from the ramus of the jaw by a quantity of adipose tissue. Its posterior border gives attachment to the Superior constrictor of the pharynx; its anterior border, to the fibres of the Buccinator.

The Bucco-pharyngeal fascia (fascia buccopharyngea) is a thin fascia covering the external surface of the Buccinator muscle. It is gradually lost in front of the angle of the mouth. Posteriorly it is continued over the external surface of the throat muscles. Its thickened cord-like portion is the stylo-mandibular ligament.

The Risorius or Santorini's Muscle (m. risorius) (Fig. 260) consists of a narrow bundle of fibres which arises in the fascia over the Masseter muscle, and, passing horizontally forward, is inserted with the Depressor anguli oris into the subcutaneous and muscular tissue at the angle of the mouth. It is placed
superficial to the Platysma, and is broadest at its outer extremity. This muscle varies much in its size and form.

**Nerves.**—The muscles in this group are all supplied by the facial nerve. The buccal branch of the inferior maxillary nerve pierces the Buccinator muscle, and by some anatomists is regarded as partly supplying this muscle. Probably it merely pierces it on its way to the mucous membrane of the cheek.

**Actions.**—The Orbicularis oris in its ordinary action produces the direct closure of the lips; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forward. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (*buccina*, a trumpet). The Risorius retracts the angles of the mouth, and produces the unpleasant expression which is sometimes seen in tetanus, and is known as *risus sardonicus*, the sardonic laugh.

9. The Temporo-mandibular Region.

**Masseter.**

The *Masseteric Fascia* (*fascia parotideomasseterica*) covers the outer and inner surfaces of the parotid gland as a thick membrane, called the *parotid fascia*. It passes forward, and becomes thinner to cover the Masseter muscle, to which it is firmly connected. It is derived from the deep cervical fascia. *Above*, this fascia is attached to the lower border of the zygoma. It is lost in front below the Risorius and Platysma.

The *Masseter Muscle* is exposed by the removal of this fascia (Fig. 260); it is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, superficial and deep. The *superficial portion*, the larger, *arises* by a thick, tendinous aponeurosis from the malar process of the superior maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch; its fibres pass downward and backward, to be *inserted* into the angle and lower half of the outer surface of the ramus of the jaw. The *deep portion* is much smaller and more muscular in texture; it *arises* from the posterior third of the lower border and the whole of the inner surface of the zygomatic arch; its fibres pass downward and forward, to be *inserted* into the upper half of the ramus and outer surface of the coronoid process of the jaw. The deep portion of the muscle is partly concealed, in front by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are united at their insertion.

**Relations.**—By its *superficial surface*, with the Zygomatici, the parotid gland and Socia parotidis, and Stenson’s duct; the branches of the facial nerve and the transverse facial vessels, which cross it; the masseteric fascia; the Risorius, Platysma myoides, and the integument; by its *deep surface*, with the Temporal muscle at its insertion, the ramus of the jaw, the Buccinator and the long buccal nerve, from which it is separated by a mass of fat (suctorial or sucking pad). The masseteric nerve and artery enter in on its under surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin* projects over the Buccinator muscle, and the facial vein lies on it below.

**Temporal Fascia** (*fascia temporalis*).—The temporal fascia is seen, at this stage of a dissection, covering in the Temporal muscle. It is a strong, fibrous investment, covered, on its outer surface, by the Attraheins and Attollens auriculam muscles, the aponeurosis of the Occipito-frontalis, and by part of the Orbicularis palpebrarum. The temporal vessels and the auriculo-temporal nerve cross it from below upward. *Above*, it is a single layer, attached to the entire extent of the upper tem-
poral ridge; but below, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner, border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital, or temporo-malar, branch of the superior maxillary nerve are contained between these two layers. It affords attachment by its inner surface to the superficial fibres of the Temporal muscle.

Dissection.—In order to expose the Temporal muscle, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma, and dissecting it upward from the surface of the muscle. The zygomatic arch should then be divided in front at its junction with the malar bone, and behind near the external auditory meatus, and drawn downward with the Masseter, which should be detached from its insertion into the ramus and angle of the jaw. The whole extent of the Temporal muscle is then exposed.

The Temporal Muscle (m. temporalis) (Figs. 264 and 265) is a broad, radiating muscle situated at the side of the head and occupying the entire extent of the temporal fossa. It arises from the whole of the temporal fossa except that portion of it that is formed by the malar bone. Its attachment extends from the external angular process of the frontal in front to the mastoid portion of the temporal behind, and from the curved line on the frontal and parietal bones above to the pterygoid ridge on the great wing of the sphenoid below. It is also attached to the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in an aponeurosis, the fibres of which, radiated at its commencement, converge into a thick and flat tendon, which is inserted into the inner surface, apex, and anterior border of the coronoid process of the jaw, nearly as far forward as the last molar tooth.

Relations.—By its superficial surface, with the integument, the Attrahens and Attollens auriculam muscles, the temporal vessels and nerves, the aponeurosis of the Occipito-frontalis, the temporal fascia, the zygoma, and Masseter; by its deep surface, with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery and its deep temporal branches, and the deep temporal nerves. Behind the tendon are the masseteric vessels and nerve, and in front of it the buccal vessels and nerve. Its anterior border is separated from the malar bone by a mass of fat.

Nerves.—Both muscles are supplied by the inferior maxillary nerve.
10. The Pterygo-mandibular Region (Figs. 266, 267).

External pterygoid.  

**Dissection.**—The Temporal muscle having been examined, saw through the base of the coronoid process, and draw it upward, together with the Temporal muscle, which should be detached from the surface of the temporal fossa. Divide the ramus of the jaw just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment, and the Pterygoid muscles will be exposed.

The **External Pterygoid Muscle** (*m. pterygoideus externus*) is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the jaw. It *arises* by two heads, separated by a slight interval: the *upper head* *arises* from the inferior surface of the greater wing of the sphenoid and from the pterygoid ridge, which separates the zygomatic from the temporal fossa; the *lower head* from the outer surface of the external pterygoid plate. Its fibres pass horizontally backward and outward, to be *inserted* into a depression in front of the neck of the condyle of the lower jaw and into the corresponding part of the interarticular fibro-cartilage.

Relations.—By its *external surface*, with the ramus of the lower jaw, the internal maxillary artery, which crosses it,¹ the tendon of the Temporal muscle, and the Masseter; by its *internal surface* it rests against the upper part of the Internal pterygoid muscle, the internal lateral ligament, the middle meningeal artery, and inferior maxillary nerve; by its *upper border* it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its *lower border* it is in relation with the inferior dental and gustatory nerves. Through the interval between the two portions of the muscle, the buccal nerve emerges and the internal maxillary artery passes, when the trunk of this vessel lies on the muscle.

The **Internal Pterygoid Muscle** (*m. pterygoideus internus*) is a thick, quadrilateral muscle, and resembles the Masseter in form. It *arises* from the pterygoid fossa, being attached to the inner surface of the external pterygoid plate and to

---

¹ This is the usual relation, but in many cases the artery will be found below the muscle.
the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosities of the palate and superior maxillary bones; its fibres pass downward, outward, and backward, to be inserted, by a strong, tendinous lamina, into the lower and back part of the inner side of the ramus and angle of the lower jaw, as high as the dental foramen.

**Relations.**—By its *external surface*, with the ramus of the lower jaw, from which it is separated, at its upper part, by the External pterygoid muscle, the internal lateral ligament, the internal maxillary artery, the dental vessels and nerves, and the lingual nerve, and a process of the parotid gland. By its *internal surface*, with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

![Fig. 267. Pterygoid muscles, viewed from behind, the back portion of the skull having been removed. (Testut.)](image-url)

**Nerves.**—These muscles are supplied by the inferior maxillary nerve.

**Actions.**—The Temporal and Masseter and Internal pterygoid raise the lower jaw against the upper with great force. The superficial portion of the Masseter assists the External pterygoid in drawing the lower jaw forward upon the upper, the jaw being drawn back again by the deep fibres of the Masseter and posterior fibres of the Temporal. The External pterygoid muscles are the direct agents in the trituration of the food, drawing the lower jaw directly forward, so as to make the lower teeth project beyond the upper. If the muscle of one side acts, the corresponding side of the jaw is drawn forward, and, the other condyle remaining fixed, the symphysis deviates to the opposite side. The alternation of these movements on the two sides produces trituration.
MUSCLES AND FASCIAE OF THE NECK

The outline of the muscles of the head and face cannot be traced on the surface of the body, except in the case of two of the masticatory muscles. Those of the head are thin, so that the outline of the bone is perceptible beneath them. Those in the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed, but they serve to round off and smooth prominent borders and to fill up what would be otherwise, unsightly angular depressions. Thus, the Orbicularis palpebrarum rounds off the prominent margin of the orbit, and the Pyramidalis nasi fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed bone. In like manner, the labial muscles, converging to the lips and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it; hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of the parts, so as to produce the varied expressions with which the face is endowed; hence these muscles are termed the muscles of expression. The only two muscles in this region which greatly influence surface form are the Masseter and the Temporal. The Masseter is a quadrilateral muscle, which imparts fullness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fulness, especially marked at the lower part of the muscle; this fulness is entirely lost when the mouth is opened and the muscle no longer in a state of contraction. The Temporal muscle is fan-shaped, and fills the Temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

MUSCLES AND FASCIAE OF THE NECK.

The muscles of the neck may be arranged into groups corresponding with the region in which they are situated.

These groups are nine in number:

1. Superficial Cervical Region.
2. Depressors of the Os Hyoideum and Larynx.
3. Elevators of the Os Hyoideum and Larynx.
4. Muscles of the Tongue.
5. Muscles of the Pharynx.
7. Muscles of the Anterior Vertebral Region.
8. Muscles of the Lateral Vertebral Region.

The muscles contained in each of these groups are the following:

1. Superficial Region.
   Platysma myoides.
   Sterno-cléido-mastoid.
   Infra-hyoid Region.
   2. Depressors of Os hyoideum and Larynx.
      Sterno-hyoid.
      Sterno-thyroid.
      Thyro-hyoid.
      Omo-hyoid.

   Supra-hyoid Region.
   3. Elevators of Os hyoideum and Larynx.
      DIGASTRIC.
      Stylo-hyoid.
      Mylo-hyoid.
      GENIO-hyoid.
      4. Muscles of the Tongue.
      LINGUAL Region.
      GENIO-HYO-GLOSSUS.
      HYO-GLOSSUS.
      CHONDRO-GLOSSUS.
      STYLO-GLOSSUS.
      PALATO-GLOSSUS.
      5. Muscles of the Pharynx.
      Inferior constrictor.
      Middle constrictor.
      Superior constrictor.
      Stylo-pharyngeus.
      Palato-pharyngeus.
6. **Muscles of the Soft Palate.**

- Levator palatii.
- Tensor palatii.
- Azigos uvulae.
- Palato-glossus.
- Palato-pharyngeus.
- Salpingo-pharyngeus.

8. **Muscles of the Lateral Vertebral Region.**

- Scalenus anticus.
- Scalenus medius.
- Scalenus posticus.

7. **Muscles of the Anterior Vertebral Region.**

- Rectus capitis anticus major.
- Rectus capitis anticus minor.
- Rectus capitis lateralis.
- Longus colli.

9. **Muscles of the Larynx.**

Included in description of the Larynx.

1. **The Superficial Cervical Region.**

**Platysma myoides.**

**Sterno-cleido-mastoid.**

**Dissection.**—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions: one from the chin, along the margin of the lower jaw, to the mastoid process, and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sterno-mastoid muscle, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in Fig. 257, the superficial fascia will be exposed.

**Superficial Cervical Fascia.**—The superficial cervical fascia is a thin, apon-eurotic lamina which is hardly demonstrable as a separate membrane. Beneath it is found the Platysma myoides muscle.

The **Platysma Myoides** (m. platysma) (Fig. 260) is a broad, thin plane of muscular fibres placed immediately beneath the superficial fascia on each side of the neck. It arises by thin, fibrous bands from the fascia covering the upper part of the Pectoral and Deltoid muscles; its fibres pass over the clavicle and proceed obliquely upward and inward along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres pass over the lower jaw, some of them being attached to the bone below the external oblique line, others passing on to be inserted into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles or to the margin of the Orbicularis oris. Beneath the Platysma the external jugular vein may be seen descending in a line from the angle of the jaw to the middle of the clavicle.

**Relations.**—By its *external surface*, with the integument, to which it is united more closely below than above; by its *internal surface*, with the Pectoralis major and Deltoid, and with the clavicle. In the *neck*, with the external and anterior jugular veins, the deep cervical fascia, the superficial branches of the cervical plexus, the Sterno-mastoid, Sterno-hyoid, Omo-hyoid, and Digastric muscles; behind the Sterno-mastoid muscle it covers in the posterior triangle of the neck. On the *face* it is in relation with the parotid gland, the facial artery and vein, and the Masseter and Buccinator muscles.

**Nerves.**—The lower division of the facial nerve chiefly innervates this muscle, and superficial branches from the cervical plexus also reach it.

**Action.**—The Platysma myoides produces a slight wrinkling of the surface of the skin of the neck, in an oblique direction, when the entire muscle is brought into action. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth on each side, being one of the chief agents in the expression of melancholy. In the pressure upon the blood-vessels of the neck induced by strong inspiratory effort,
this muscle draws away the skin and fascia, and by so doing, greatly diminishes the pressure on the veins.

**Deep Cervical Fascia** (fascia colli) (Fig. 268).—The deep cervical fascia lies under cover of the Platysma myoides muscle and constitutes a complete investment for the neck. It also forms a sheath for the carotid vessels, and, in addition, is prolonged deeply in the shape of certain processes or lamellae, which come into close relation with the structures situated in front of the vertebral column.

The investing portion of the fascia is attached, *behind*, to the ligamentum nuchae and to the spine of the seventh cervical vertebra. Along this line it splits to enclose the Trapezius muscle, at the anterior border of which the two enclosing lamellae unite and form a strong membrane, which extends forward so as to roof in the posterior triangle of the neck. Along the hinder edge of the Sterno-mastoid the membrane divides to enclose this muscle, at the anterior edge of which it once more forms a single lamella, which roofs in the anterior triangle of the neck, and, reaching forward to the middle line, is continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is attached to the symphysis menti and to the body of the hyoid bone.
Above, the fascia is attached to the superior curved line of the occiput, to the mastoid process of the temporal, and to the whole length of the body of the jaw. Opposite the angle of the jaw the fascia is very strong, and binds the anterior edge of the Sterno-mastoid firmly to that bone. Between the jaw and the mastoid process it ensheaths the parotid gland—the layer which covers the gland extending upward under the name of the parotid fascia to be fixed to the zygomatic arch. The parotid fascia is prolonged forward to cover the masseter muscle, the masseteric fascia. From the layer which passes under the parotid a strong band, the stylo-mandibular ligament, reaches from the styloid process to the angle of the jaw. The parotid and masseteric fasciae constitute the fascia parotideomasseterica.

Below, the cervical fascia is attached to the acromion process, the clavicle, and to the manubrium sterni. Some little distance above the last-named point, however, it splits into two layers, superficial and deep. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers is a slit-like interval, the suprasternal space or space of Burns (spatium suprasternale). It contains a small quantity of areolar tissue, and sometimes a lymphatic gland; the lower portions of the anterior jugular veins and their transverse connecting branch; and also the sternal heads of the Sterno-mastoid muscles.

The fascia which lines the deep aspect of the Sterno-mastoid gives off certain important processes, viz.: (1) A process to envelop the tendon of the Omo-hyoid, and bind it down to the sternum and first costal cartilage. (2) A strong sheath, the carotid sheath, for the large vessels of the neck, enclosed within which are the carotid artery, internal jugular vein, the vagus, and descendens hypoglossi nerves. (3) The prevertebral fascia (fascia prevertebralis), which extends inward behind the carotid vessels, where it assists in forming their sheath, and passes in front of the prevertebral muscles. It thus forms the posterior limit of a fibrous compartment which contains the larynx and trachea, the thyroid gland, and the pharynx and oesophagus. The prevertebral fascia is fixed above to the base of the skull, while below it is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid vessels and along their inner aspect it gives off a thin lamina, the bucco-pharyngeal fascia (fascia buccopharyngea), which closely invests the constrictor muscles of the pharynx, and is continued forward from the Superior constrictor on to the Buccinator. It is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the retro-pharyngeal space (spatium retropharyngea), is found between them. This space is limited above by the base of the skull, while below it extends behind the oesophagus into the thorax, where it is continued into the posterior mediastinum. The prevertebral fascia is prolonged downward and outward behind the carotid vessels and in front of the Scaleni muscles, and forms a sheath for the brachial plexus of nerves and for the subclavian vessels in the posterior triangle of the neck, and, continuing under the clavicle as the axillary sheath, is attached to the deep surface of the costo-coracoid membrane. Immediately above the clavicle an areolar space exists between the investing layer and the sheath of the subclavian vessels, and in it are found the lower part of the external jugular vein, the descending clavicular nerves, the suprascapular and transversalis colli vessels, and the posterior belly of the Omo-hyoid muscle. This space extends downward behind the clavicle, and is limited below by the fusion of the costo-coracoid membrane with the anterior wall of the axillary sheath. (4) The pre-tracheal fascia, which extends inward in front of the carotid vessels, and assists in forming the carotid sheath. It is further continued behind the Depressor muscles of the hyoid bone, and, after enveloping the thyroid body, is prolonged in front of the trachea to meet the corresponding layer of the opposite side. Above, it is fixed to the hyoid
Actions.—When only one Stermo-mastoid muscle acts, it draws the head toward the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face toward the opposite side. When the two muscles act together they flex the head upon the neck. If the head is fixed, the two muscles assist in elevating the thorax in forced inspiration.

Surface Form.—The anterior edge of the muscle forms a very prominent ridge beneath the skin, which it is important to notice, as it forms a guide to the surgeon in making the necessary incisions for ligature of the common carotid artery and for oesophagotomy.

Surgical Anatomy.—The relations of the sternal and clavicular parts of the Stermo-mastoid should be carefully examined, as the surgeon is sometimes required to divide one or both portions of the muscle in _surg-necis_ (torticollis). One variety of this distortion is produced by spasmodic contraction or rigidity of the Stermo-mastoid; the head being carried down toward the shoulder of the same side, and the face turned to the opposite side and fixed in that position. When there is permanent shortening, _subcutaneous division_ of the muscle is resorted to by some surgeons. This is performed by introducing a tenotomy knife beneath it, close to its origin, and dividing it from behind forward whilst the muscle is put well upon the stretch. There is seldom any difficulty in dividing the sternal portion by making a puncture on the inner side of the tendon, and then pushing a blunt tenotomy behind it, and cutting forward. In dividing the clavicular portion care must be taken to avoid wounding the external jugular vein, which runs parallel with the posterior border of the muscle in this situation, or the anterior jugular vein, which crosses beneath it. If the external jugular vein lies near the muscle, it is safer to make the first puncture at the outer side of the tendon, and introduce a blunt tenotomy from without inward. Many surgeons prefer dividing the muscle by open incision, because by this method all of the contracted fibres, muscular and facial, can be certainly and safely divided. An incision is made over the origin of the muscle, the origin is exposed, a director is passed underneath it, and it is then divided. With care and attention to aspais this plan of treatment is devoid of risk, and in this way the accidental division of vessels can be avoided. Some of the fibres of the Stermo-mastoid muscle are occasionally torn during birth, especially in breech presentations; this is accompanied by hemorrhage and formation of a swelling within the substance of the muscle. This by some is believed to be one of the causes of wry-neck, the scar tissue which is formed contracting and shortening the muscle.

2. The Infra-hyoid Region (Figs. 269, 270).

**Depressors of the Os Hysterideum and Larynx.**

- Stermo-hyoid.
- Thyro-hyoid.
- Sterno-thyroid.
- Omohyoid.

**Dissection.**—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the Omohyoid it is necessary to divide the sterno-mastoid at its centre, and turn its ends aside, and to detach the Trapezius from the clavicle and scapula. This, however, should not be done until the Trapezius has been dissected.

The Stermo-hyoid (m. sternohyoides) is a thin, narrow, ribbon-like muscle, which arises from the inner extremity of the clavicle, the posterior sternoclavicular ligament, and the upper and posterior part of the first piece of the sternum; passing upward and inward, it is inserted, by short, tendinous fibres, into the lower border of the body of the hyoid bone. This muscle is separated, below, from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and from this upward lie side by side. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the Rectus abdominis. As a rule, two bursae, the sterno-hyoid bursa (bursa sternohyoidi), lie between the crico-thyroid membrane, on one hand, and the Sterno-hyoid muscle and the cervical fascia, on the other. Sometimes there is one large median bursa instead of two lateral bursae. Not unusually there is no bursa at all.

**Relations.**—By its superficial surface, below, with the sternum, the sternal end of the clavicle, and the Sterno-mastoid; and above, with the Platysma and deep cervical fascia; by its deep surface, with the Sterno-thyroid, Crico-thyroid, and
Thyro-hyoid muscles, the thyroid gland, the superior thyroid vessels, the thyroid cartilage, the crico-thyroid and thyro-hyoid membranes.

The Sterno-thyroid (m. sternothyreoides) is situated beneath the preceding muscle, but is shorter and wider than it. It arises from the posterior surface of the first piece of the sternum, below the origin of the Sterno-hyoid, and from the edge of the cartilage of the first rib, occasionally of the second rib also, and is inserted into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck, and is occasionally traversed by a transverse or oblique tendinous intersection, like those in the Rectus abdominis.

Relations.—By its anterior surface, with the Sterno-hyoid, Omo-hyoid, and Sterno-mastoid; by its posterior surface, from below upward, with the trachea, vena innominata, common carotid (and on the right side the arteria innominata), the thyroid gland and its vessels, and the lower part of the larynx and pharynx. The inferior thyroid vein lies along its inner border, a relation which it is important to remember in the operation of tracheotomy. On the left side the deep surface of the muscle is in relation to the oesophagus.

The Thyro-hyoid (m. thyreohyoides) is a small, quadrilateral muscle appearing like a continuation of the Sterno-thyroid. It arises from the oblique line on the side of the thyroid cartilage, and passes vertically upward to be inserted into the lower border of the body and greater cornu of the hyoid bone. The thyro-hyoid bursae (bursa thyreohyoidii) lie inferior to the greater cornua of the hyoid bone and upon the thyro-hyoid membrane. There is one bursa on each side beneath the corresponding Thyro-hyoid muscle.

Relations.—By its external surface, with the Sterno-hyoid and Omo-hyoid muscles; by its internal surface, with the thyroid cartilage, the thyro-hyoid membrane, and the superior laryngeal vessels and nerve.
The Omo-hyoid (m. omohyoides) passes across the side of the neck, from the scapula to the hyoid bone. It consists of two fleshy bellies, united by a central tendon. It arises from the upper border of the scapula, and occasionally from the transverse ligament which crosses the suprascapular notch, its extent of attachment to the scapula varying from a few lines to an inch. From this origin the posterior belly (venter inferior) forms a flat, narrow fasciculus, which inclines forward and slightly upward across the lower part of the neck, behind the Sterno-mastoid muscle, where it becomes tendinous; it then changes its direction, forming an obtuse angle, and terminates in the anterior belly (venter superior), which passes almost vertically upward, close to the outer border of the Sterno-hyoid, to be inserted into the lower border of the body of the hyoid bone, just external to the insertion of the Sterno-hyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which includes it in a sheath. This process is prolonged down, to be attached to the clavicle and first rib. It is by this means that the angular form of the muscle is maintained.

This muscle subdivides each of the two large triangles at the side of the neck into two smaller triangles; the two posterior ones being the posterior superior or occipital triangle, and the posterior inferior or subclavian triangle; the two anterior, the anterior superior or superior carotid triangle, and the anterior inferior or inferior carotid triangle.

Relations.—By its superficial surface, with the Trapezius, the Sterno-mastoid, deep cervical fascia, Platysma, and integument; by its deep surface, with the Scaleni muscles, phrenic nerve, lower cervical nerves, which go to form the brachial plexus, the suprascapular vessels and nerve, sheath of the common carotid artery and internal jugular vein, the Sterno-thyroid and Thyro-hyoid muscles.

Nerves.—The Thyro-hyoid is supplied by the hypoglossal; the other muscles of this group by branches from the loop of communication between the descendens and communicans hypoglossi.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omo-hyoid muscles not only depress the hyoid bone, but carry it backward and to one side. It is concerned especially in prolonged inspiratory efforts; for by tensing the lower part of the cervical fascia it lessens the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. This action is synergistic with that of the Platysma. The Thyro-hyoid may act as an elevator of the thyroid cartilage when the hyoid bone ascends, drawing upward the thyroid cartilage, behind the hyoid bone. The Sterno-thyroid acts as a depressor of the thyroid cartilage.

3. The Supra-hyoid Region (Figs. 269, 270).

Elevators of the Os Hyoideum—Depressors of the Lower Jaw.

Digastric. Stylo-hyoid.

Dissection.—To dissect these muscles a block should be placed beneath the back of the neck, and the head drawn backward and retained in that position. On the removal of the deep fascia the muscles are at once exposed.

The Digastric (m. digastricus) consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the side of the body of the lower jaw, and extending, in a curved form, from the side of the head to the symphysis of the jaw. The posterior belly (venter posterior), longer than the anterior, arises from the digastric groove on the inner side of the mastoid process of the temporal bone, and passes downward, forward, and inward.
The **anterior belly** (*venter anterior*) **arises** from a depression on the inner side of the lower border of the jaw, close to the symphysis, and passes downward and backward. The two bellies terminate in the central tendon which perforates the Stylo-hyoid, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined by a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on each side, which is attached to the body and great cornu of the hyoid bone: this is termed the **supra-hyoid aponeurosis**. It forms a strong layer of fascia between the anterior portion of the two muscles, and a firm investment for the other muscles of the supra-hyoid region which lie deeper.

The Digastric muscle divides the anterior superior triangle of the neck into two smaller triangles; the **upper**, or **submaxillary triangle**, being bounded, above, by the lower border of the body of the jaw, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and the Stylo-hyoid muscles; in front, by the middle line of the neck and the anterior belly of the Digastric, the **lower** or **superior carotid triangle** being bounded above by the posterior belly of the Digastric, behind by the Sterno-mastoid, below by the anterior belly of the Omo-hyoid.

**Relations.**—By its **superficial surface**, with the mastoid process, the Platysma, Sterno-mastoid, part of the Spleenius, Trachelo-mastoid, and Stylo-hyoid muscles, and the parotid gland. By its **deep surface**, the anterior belly lies on the Mylo-hyoid; the posterior belly on the Stylo-glossus, Stylo-pharyngeus, and Hyo-glossus muscles, the external carotid artery and its occipital, lingual, facial, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylo-hyoid** (*m. stylohyoideus*) is a small, slender muscle, lying in front of, and above, the posterior belly of the Digastric. It **arises** from the back and outer surface of the styloid process of the temporal bone, near the base; and, passing downward and forward, is **inserted** into the body of the hyoid bone, just at its junction with the greater cornu, and immediately above the Omo-hyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

**Relations.**—By its **superficial surface** above with the parotid gland and deep cervical fascia; below it is superficial, being situated immediately beneath the deep cervical fascia. By its **deep surface**, with the posterior belly of the Digastric, the external carotid artery, with its lingual and facial branches, the Hyo-glossus muscle, and the hypoglossal nerve.

The **Stylo-hyoid Ligament** (*ligamentum stylohyoideus*).—In connection with the Stylo-hyoid muscle may be described a ligamentous band, the **stylo-hyoid ligament**. It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and the small cornu of the latter. It is often more or less ossified, and in many animals forms a distinct bone, the **eiphyal**.

The anterior belly of the Digastric should be removed, in order to expose the next muscle.

The **Mylo-hyoid** (*m. mylohyoideus*) (Fig. 271) is a flat, triangular muscle, situated immediately beneath the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It **arises** from the whole length of the mylo-hyoid ridge of the lower jaw, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass inward and slightly downward, to be inserted into the body of the hyoid bone. The middle and anterior fibres are inserted into a median fibrous raphé, extending from the symphysis of the lower jaw to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. The median raphé
is sometimes wanting; the muscular fibres of the two sides are then directly continuous with one another.

**Relations.**—By its cutaneous or under surface, with the Platysma, the anterior belly of the Digastric, the supra-hyoid aponeurosis, the submaxillary gland, submental vessels, and mylo-hyoid vessels and nerve; by its deep or superior surface, with the Genio-hyoid, part of the Hyo-glossus and Stylo-glossus muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland, and Wharton's duct; the sublingual and ranine vessels, and the buccal mucous membrane.

**Dissection.**—The Mylo-hyoid should now be removed, in order to expose the muscles which lie beneath; this is effected by reflecting it from its attachments to the hyoid bone and jaw, and separating it by a vertical incision from its fellow of the opposite side.

![Fig. 271.—Mylo-hyoid muscle. (Poirier and Charpy.)](image-url)

The **Genio-hyoid** (*m. geniohyoides*) (Fig. 272) is a narrow, slender muscle, situated immediately beneath the inner border of the preceding. It arises from the inferior genial tubercle on the inner side of the symphysis of the jaw, and passes downward and backward, to be inserted into the anterior surface of the body of the hyoid bone. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

**Relations.**—It is covered by the Mylo-hyoid and lies along the lower border of the Genio-hyoid-glossus.

**Nerves.**—The anterior belly of the Digastric is supplied by the mylo-hyoid branch of the inferior dental; its posterior belly, by the facial; the Stylo-hyoid is supplied by the facial; the Mylo-hyoid, by the mylo-hyoid branch of the inferior dental; the Genio-hyoid, by the hypoglossal.

**Actions.**—This group of muscles performs two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition; or, when the hyoid bone is fixed by its depressors and those of the larynx, they depress the lower jaw. During the first act of deglutition, when the mass is being driven from the mouth into the pharynx, the hyoid bone, and with it the tongue, is carried upward and forward by the anterior belly of the Digastric, the Mylo-hyoid, and Genio-hyoid muscles. In the second act, when the mass is pass-

---

1 This refers to the depth of the muscles from the skin in the order of dissection. In the erect position of the body the Genio-hyoid is above the Mylo-hyoid.
ing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upward and backward by the posterior belly of the Digastric and Stylohyoid muscles, which assist in preventing the return of the morsel into the mouth.

4. The Lingual Region (Figs. 272, 273, 274).

Hyo-glossus. Palato-glossus.
Chondro-glossus.

Dissection.—After completing the dissection of the preceding muscles, saw through the lower jaw just external to the symphysis. Then draw the tongue forward, and attach it, by a stitch, to the nose; when its muscles, which are thus put on the stretch, may be examined.

The Genio-hyo-glossus (m. genioglossus) has received its name from its triple attachment to the jaw, hyoid bone, and tongue, but it is better to name it the Genio-glossus, since its attachment to the hyoid bone is very slight or altogether absent. It is a flat, triangular muscle, placed vertically on either side of the middle line, its apex corresponding with its point of attachment to the lower jaw, its base with its insertion into the tongue and hyoid bone. It arises by a short tendon from the superior genial tubercle on the inner side of the symphysis of the jaw, immediately above the Genio-hyoiid; from this point the muscle spreads out in a fan-like form, a few of the inferior fibres passing downward, to be attached by a thin aponeurosis into the upper part of the body of the hyoid bone, a few fibres passing between the Hyo-glossus and Chondro-glossus to blend with the Constrictor muscles of the pharynx; the middle fibres passing backward, and the superior ones upward and forward, to enter the whole length of the under surface of the tongue, from the base to the apex. The two muscles lie on either side of the median plane;
behind (Fig. 273), they are quite distinct from each other, and are separated at
their insertion into the under surface of the tongue by a tendinous raphe, which
extends through the middle of the organ; in front, the two muscles are more or
less blended: distinct fasciculi are to be seen passing off from one muscle, crossing
the middle line, and intersecting with bundles of fibres derived from
the muscle on the other side.

Relations.—By its internal surface it is in contact with its fellow of the opposite
side; by its external surface, with the Inferior lingualis, the Hyo-glossus, the lin-
gual artery and hypoglossal nerve, the lingual nerve, and sublingual gland; by its upper bor-
der, with the mucous membrane of the floor of the mouth (frenum linguae); by its lower border
with the Genio-hyoid.

The Hyo-glossus (m. hyoglossus) is a thin,
flat, quadrilateral muscle which arises from the
side of the body and whole length of the greater
cornu of the hyoid bone, and passes almost ver-
tically upward to enter the side of the tongue,
between the Stylo-glossus and Lingualis. Those
fibres of this muscle which arise from the body
are directed upward and backward, overlapping those arising from the greater cornu, which
are directed upward and forward.

Relations.—By its external surface, with the
Digastric, the Stylo-hyoid, Stylo-glossus, and
Mylo-hyoid muscles, the submaxillary ganglion,
the lingual and hypo-glossal nerves, Wharton’s
duct, the ranine vein, the sublingual gland, and
the deep portion of the submaxillary gland. By
its deep surface, with the Stylo-hyoid ligament,
the Genio-hyoglossus, Lingualis, and Middle
constrictor, the lingual vessels, and the glosso-
pharyngeal nerve.

The Chondro-glossus (m. chondroglossus) is
a distinct muscular slip, though it is sometimes
described as a part of the Hyo-glossus, from
which, however, it is separated by the fibres of
the Genio-hyoglossus, which pass to the side of
the pharynx. It is about three-quarters to an inch in length, and arises from the
inner side and base of the lesser cornu and contiguous portion of the body of the
hyoid bone, and passes directly upward to blend with the intrinsic muscular
fibres of the tongue, between the Hyo-glossus and Genio-hyoglossus. A small
slip of muscular fibre is occasionally found, arising from the cartilago triticia
in the thyro-hyoid ligament, and passing upward and forward to enter the
tongue with the hindermost fibres of the Hyo-glossus.

The Stylo-glossus (m. styloglossus), the shortest and smallest of the three styloid
muscles, arises from the anterior and outer side of the styloid process, near its apex,
and from the stylo-mandibular ligament, to which its fibres, in most cases, are
attached by a thin aponeurosis. Passing downward and forward between the inter-
nal and external carotid arteries, and becoming nearly horizontal in its direction,
it divides upon the side of the tongue into two portions: one longitudinal, which
enters the side of the tongue near its dorsal surface, blending with the fibres of the
Lingualis in front of the Hyo-glossus; the other oblique, which overlaps the
Hyoglossus muscle and decussates with its fibres.
**Relations.**—By its external surface, from above downward, with the parotid gland, the Internal pterygoid muscle, the lingual nerve, and the mucous membrane of the mouth; by its internal surface, with the tonsil, the Superior constrictor, and the Hyo-glossus muscle.

The **Palato-glossus** or **Constrictor Isthmi Faucium** (*m. glosso-palatinus*), although it is one of the muscles of the tongue, serving to draw its base upward during the act of deglutition, is more nearly associated with the soft palate, both in its situation and function; it will consequently be described with that group of muscles.

**Nerves.**—The Palato-glossus is probably innervated by the spinal accessory nerve, through the pharyngeal plexus; the remaining muscles of this group, by the hypo-glossal.

**Muscular Substance of the Tongue** (Figs. 273, 274, and 275).—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets—Extrinsic and Intrinsic. The **extrinsic muscles** of the tongue are those which have their origin external, and only their terminal fibres contained in the substance of the organ. They are: the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngeoglossus). The **intrinsic muscles** are those which are contained entirely within the tongue, and form the greater part of its muscular structure.

The tongue consists of symmetrical halves separated from each other in the middle line by a **fibrous septum** (*septum linguae*). Each half is composed of muscular fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves.

To demonstrate the various fibres of the tongue, the organ should be subjected to prolonged boiling, in order to soften the connective tissue; the dissection may then be commenced from the dorsum (Figs. 274 and 275). Immediately beneath the mucous membrane is a **submucous, fibrous** layer, into which the muscular fibres which terminate on the surface of the tongue are inserted. Upon removing this,
with the mucous membrane, the first stratum of muscular fibres is exposed. This belongs to the group of intrinsic muscles, and has been named the Superior lingualis (m. longitudinalis superior). It consists of a thin layer of oblique and longitudinal fibres which arise from the submucous fibrous layer, close to the Epiglottis, and from the fibrous septum, and pass forward and outward to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Genio-hyo-glossus and from the vertical intrinsic muscle, which will be described later on. Beneath this layer is the second stratum of muscular fibres, derived principally from the extrinsic muscles. In front it is formed by the fibres derived from the Stylo-glossus, running along the side of the tongue, and sending one set of fibres over the dorsum which run obliquely forward and inward to the middle line, and another set of fibres seen at a later period of the dissection, on to the under surface of the sides of the anterior part of the tongue, which run forward and inward, between the fibres of the Hyo-glossus, to the middle line. Behind this layer of fibres, derived from the Stylo-glossus, are fibres derived from the Hyo-glossus, assisted by some few fibres of the Palato-glossus. The Hyo-glossus, entering the side of the under surface of the tongue, between the Stylo-glossus and Inferior lingualis, passes round its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inward to the septum. It is reinforced by some fibres from the Palato-glossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscular fibres of the tongue is derived from those fibres of the Hyo-glossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the Chondro-glossus. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue. Beneath this layer is the great mass of the intrinsic muscles of the tongue, intersected at right angles by the terminal fibres of one of the extrinsic muscles—the Genio-hyo-glossus. This portion of the tongue is paler in color and softer in texture than that already described, and is sometimes designated the medullary portion in contradistinction to the firmer superficial part, which is termed the cortical portion. It consists largely of transverse fibres, the Transverse lingualis (m. transversus linguae), and of vertical fibres, the Vertical lingualis (m. verticalis linguae). The Transverse lingualis forms the largest portion of the third layer of muscular fibres of the tongue. The fibres arise from the median septum, and pass outward to be inserted into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palato-glossus and the Superior constrictor of the pharynx. These transverse extrinsic fibres, however, run in the opposite direction, passing inward toward the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Genio-hyo-glossus and partly from intrinsic fibres, the Vertical lingualis. The fibres derived from the Genio-hyo-glossus enter the under surface of the tongue on each side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on each side of the middle line. The Vertical lingualis is found only at the borders of the forepart of the tongue, external to the fibres of the Genio-hyo-glossus. Its fibres extend from the upper to the under surface of the organ, decussating with the fibres of the other muscles, and especially with the Transverse lingualis. The fourth layer of muscular fibres of the tongue consists partly of extrinsic fibres derived from the Stylo-glossus, and partly of intrinsic fibres, the Inferior lingualis (m. longitudinalis inferior). At the sides of the under surface of the organ are some fibres derived from the Stylo-glossus, which, as it runs forward at the side of the tongue, gives off fibres which, passing forward and inward between the fibres of the Hyo-glossus, form an inferior oblique stratum which joins in front with the
anterior fibres of the Inferior lingualis. The Inferior lingualis is a longitudinal band, situated on the under surface of the tongue, and extending from the base to the apex of the organ. Behind, some of its fibres are connected with the body of the hyoid bone. It lies between the Hyo-glossus and the Genio-hyo-glossus, and in front of the Hyo-glossus it enters into relation with the Stylo-glossus, with the fibres of which it blends. It is in relation by its under surface with the ranine artery.

**Surgical Anatomy.**—The fibrous septum which exists between the two halves of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free, a fact often illustrated by injecting one-half of the tongue with colored size, while the other half is left un.injected or is injected with size of a different color.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the anterior portion of the tongue. If the mucous membrane is divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphé without any appreciable hemorrhage, and the diseased half can then be removed.

**Actions.**—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The Genio-hyo-glossi muscles, by means of their posterior fibres, draw the base of the tongue forward, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole length of these two muscles, acting along the middle line of the tongue, draw it downward, so as to make it concave from side to side, forming a channel along which fluids may pass toward the pharynx, as in sucking. The Hyo-glossi muscles depress the tongue and draw down its sides, so as to render it convex from side to side. The Stylo-glossi muscles draw the tongue upward and backward. The Palato-glossi muscles draw the base of the tongue upward. With regard to the intrinsic muscles, both the Superior and Inferior linguales tend to shorten the tongue, but the former, in addition, turn the tip and sides upward so as to render the dorsum concave, while the latter pull the tip downward and cause the dorsum to become convex. The Transverse linguales narrows and elongates the tongue, and the Vertical linguales flattens and broadens it. The complex arrangement of the muscular fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds; and Dr. Macalister states that "there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages."

5. The Pharyngeal Region (Figs. 276, 277, 278).

**Inferior constrictor.**
**Middle constrictor.**
**Palato-pharyngeus.**
**Salpingo-pharyngeus.**

(See next section.)

**Dissection** (Fig. 276).—In order to examine the muscles of the pharynx, cut through the trachea and oesophagus just above the sternum, and draw them upward by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forward, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upward. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The **Inferior Constrictor** (*m. constrictor pharyngis inferior*), the most superficial and thickest of the three constrictors, arises from the sides of the cricoid and thyroid cartilages. To the cricoid cartilage it is attached in the interval between
the Crico-thyroid muscle in front and the articular facet for the thyroid cartilage behind. To the thyroid cartilage it is attached to the oblique line on the side of the great ala, the cartilaginous surface behind it, nearly as far as its posterior border, and to the inferior cornu. From these attachments the fibres spread backward and inward, to be inserted into the fibrous raphé in the posterior median line of the pharynx. The inferior fibres are horizontal, and continuous with the fibres of the oesophagus: the rest ascend, increasing in obliquity, and overlap the Middle constrictor.

Relations.—It is covered by a thin membrane which surrounds the entire pharynx, bucco-pharyngeal fascia (fascia buccopharyngea). Behind, it is in relation with the vertebral column and the prevertebral fascia and muscles; laterally, with the thyroid gland, the common carotid artery, and the Sterno-thyroid muscle; by its internal surface, with the Middle constrictor, the Stylo-pharyngeus, Palato-pharyngeus, the fibrous coat and mucous membrane of the pharynx. The internal laryngeal nerve and the laryngeal branch of the Superior Thyroid artery pass near the upper border, and the inferior, or recurrent laryngeal nerve, and the laryngeal branch of the Inferior Thyroid artery, beneath the lower border of this muscle, previous to their entering the larynx.

The Middle Constrictor (m. constrictor pharyngis medius) is a flattened, fan-shaped muscle, smaller than the preceding. It arises from the whole length of the upper border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylohyoid ligament. The fibres diverge from their origin, the lower ones descending beneath the Inferior constrictor, the middle fibres passing transversely, and the upper fibres ascending and overlapping the Superior constrictor. The muscle is inserted into the posterior median fibrous raphé, blending in the middle line with the one of the opposite side.

Relations.—Between this muscle and the Superior constrictor are the glossopharyngeal nerve, the Stylo-pharyngeus muscle and the stylo-hyoid ligament; and between it and the Inferior constrictor is the superior laryngeal nerve. Behind, it lies on the vertebral column, the Longus colli, and the Rectus capitis anticus major. On each side it is in relation with the carotid vessels, the pharyngeal plexus, and some lymphatic glands. Near its origin it is covered by the Hyo-glossus, the lingual vessels being placed between the two muscles. It lies upon the Superior constrictor, the Stylo-pharyngeus, the Palato-pharyngeus, the fibrous coat, and the mucous membrane of the larynx.

The Superior Constrictor (m. constrictor pharyngis superior) is a quadrilateral muscle, thinner and paler than the other constrictors, and situated at the upper part of the pharynx. It arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process, from the contiguous portion of the
palate bone and the reflected tendon of the Tensor palati muscle, from the pterygo-maxillary ligament, from the alveolar process above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue. From these points the fibres curve backward, to be inserted into the median raphé, being also prolonged by means of a fibrous aponeurosis to the pharyngeal spine on the basilar process of the occipital bone. The superior fibres arch beneath the Levator palati and the Eustachian tube, the interval between the upper border of the muscle and the basilar process being deficient in muscular fibres and closed by a portion of the pharyngeal aponeurosis (fascia pharyngobasilaris). This interval is known as the sinus of Morgagni.

Fig. 277.—The muscles of the pharynx. On the right side most of the inferior constrictor has been removed, on the left side the Digastric and Stylo-hyoid have been removed. (Spalteholz.)

Relations.—By its outer surface, with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the internal jugular vein and pharyngeal venous plexus, the glosso-pharyngeal, pneumogastric, spinal accessory, hypoglossal, lingual, and sympathetic nerves, the Middle constrictor and Internal pterygoid muscles, the Styloid process, the Stylo-
hyoid ligament, and the Stylo-pharyngeus. By its internal surface, with the Palato-pharyngeus, the tonsil, the fibrous coat and mucous membrane of the pharynx.

The **Stylo-pharyngeus** (*m. stylopharyngeus*) is a long, slender muscle, round above, broad and thin below. It arises from the inner side of the base of the styloid process of the temporal bone, passes downward along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane, where some of its fibres are lost in the Constrictor muscles; and others, joining with the Palato-pharyngeus, are inserted into the posterior border of the thyroid cartilage. The glosso-pharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

**Relations.**—Externally, with the Stylo-glossus muscle, the parotid gland, the external carotid artery, and the Middle constrictor; internally, with the internal carotid, the internal jugular vein, the Superior constrictor, Palato-pharyngeus, and mucous membrane.

**Nerves.**—The Constrictors are supplied by branches from the pharyngeal plexus. The Inferior constrictor also receives an additional branch from the external laryngeal nerve and one from the recurrent laryngeal. The Stylo-pharyngeus is supplied by the glosso-pharyngeal nerve.

**Actions.**—When deglutition is about to be performed, the pharynx is drawn upward and dilated in different directions, to receive the morsel propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upward and outward, and so increase its transverse diameter, its breadth in the antero-posterior direction being increased by the larynx and tongue being carried forward in their ascent. As soon as the morsel is received in the pharynx, the Elevator muscles relax, the bag descends, and the Constrictors contract upon the morsel, and convey it gradually downward into the oesophagus. Besides its action in deglutition, the pharynx also exerts an important influence in the modulation of the voice, especially in the production of the higher tones.

### 6. The Palatal Region (Fig. 278.)

- Levator palati.
- Tensor palati.
- Azygos uvulae.

**Palato-glossus.**

**Palato-pharyngeus.**

**Salpingo-pharyngeus.**

**Dissection** (Fig. 278).—Lay open the pharynx from behind by a vertical incision extending from its upper to its lower part, and partially divide the occipital attachment by a transverse incision on each side of the vertical one; the posterior surface of the soft palate is then exposed. Having fixed the uvula so as to make it tense, the mucous membrane and glands should be carefully removed from the posterior surface of the soft palate, and the muscles of this part are at once exposed.

The **Levator Palati** (*m. levator veli palatini*) is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous portion of the temporal bone, and from the inner surface of the cartilaginous portion of the Eustachian tube; after passing into the pharynx, above the upper concave margin of the Superior constrictor, it passes obliquely downward and inward, its fibres spreading out in the soft palate as far as the middle line, where they blend with those of the opposite side.

**Relations.**—Externally, with the Tensor palati and Superior constrictor and Eustachian tube; internally, with the mucous membrane of the pharynx; posteriorly, with the posterior fasciculus of the Palato-pharyngeus, the Azygos uvulae, and the mucous lining of the soft palate.
The **Circumflexus** or **Tensor Palati** (*m. tensor veli palatini*) is a broad, thin, ribbon-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal portion. The **vertical portion arises** by a flat lamella from the scaphoid fossa at the base of the internal pterygoid plate; from the spine of the sphenoid and the outer side of the cartilaginous portion of the Eustachian tube: descending vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, it terminates in a tendon, which winds round the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle. Between the hamular process and the tendon is a small bursa (*bursa m. tensoris veli palati*). The **tendon or horizontal portion** then passes horizontally inward, and is inserted into a broad aponeurosis, the **palatine aponeurosis**, and into the transverse ridge on the horizontal portion of the palate bone.

**Relations.**—*Externally*, with the Internal pterygoid; *internally*, with the Levator palati, from which it is separated by the Eustachian tube and Superior constrictor and with the internal pterygoid plate. In the soft palate its tendon and the palatine aponeurosis are anterior to those of the Levator palati, being covered by the Palato-glossus and the mucous membrane.

**Palatine Aponeurosis.**—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

![Fig. 278.—Muscles of the soft palate, the pharynx being laid open from behind.](image-url)
The **Azygos Uvulae** (*m. uvulae*) is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi placed on either side of the median line of the soft palate. Each muscle *arises* from the posterior nasal spine of the palate bone and from the contiguous tendinous aponeurosis of the soft palate, and descends to be inserted into the uvula.

**Relations.**—*Anteriorly*, with the tendinous expansion of the Levatores palati; *behind*, with the posterior fasciculus of the Palato-pharyngeus and the mucous membrane.

The next two muscles are exposed by removing the mucous membrane from the pillars of the fauces throughout nearly their whole extent.

The **Palato-glossus** or the **Constrictor Isthmi Fauccium** (*m. glossopalatinus*) is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the soft palate. It *arises* from the anterior surface of the soft palate on each side of the uvula, and, passing downward, forward, and outward in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transverse lingualis. In the soft palate the fibres of this muscle are continuous with those of the muscle of the opposite side.

The **Palato-pharyngeus** (*m. pharyngopalatinus*) is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the soft palate. It is separated from the Palato-glossus by an angular interval, in which the tonsil is lodged. It *arises* from the soft palate by an expanded fasciculus, which is divided into two parts by the Levator palati and Azygos uvulae. The **posterior fasciculus** lies in contact with the mucous membrane, and also joins with the corresponding muscle in the middle line; the **anterior fasciculus**, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing outward and downward behind the tonsil, the Palato-pharyngeus joins the Stylo-pharyngeus, and is *inserted* with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly to decussate with the muscle of the opposite side.

**Relations.**—In the soft palate its **posterior surface** is covered by mucous membrane, from which it is separated by a layer of palateine glands. By its **anterior surface** it is in relation with the Tensor palati. Where it forms the posterior pillar of the fauces it is covered by mucous membrane, excepting on its outer surface. In the **pharynx** it lies between the mucous membrane and the Constrictor muscles.

The **Salpingo-pharyngeus** *arises* from the inferior part of the Eustachian tube near its orifice; it passes downward and blends with the posterior fasciculus of the Palato-pharyngeus.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order—viz., the posterior fasciculus of the Palato-pharyngeus, covered over by the mucous membrane reflected from the floor of the nasal fossae; the Azygos uvulae; the Levator palati; the anterior fasciculus of the Palato-pharyngeus; the aponeurosis of the Tensor palati, and the Palato-glossus, covered over by a reflection from the oral mucous membrane.

**Nerves.**—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the internal branch of the spinal accessory, whose fibres are distributed along with certain branches of the pneumogastric through the pharyngeal plexus. 1 It is possible,

---

however, that the Levator palati may be supplied by the facial through the Petroso branch of the Vidian.

Actions.—During the first stage of deglutition the morsel of food is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx, and carried forward under it. During the second stage the entrance to the larynx is closed, not, as was formerly supposed, by the folding backward of the epiglottis over it, but, as Anderson Stuart has shown, by the drawing forward of the arytenoid cartilages toward the cushion of the epiglottis—a movement produced by the contraction of the External thyro-arytenoid, the Arytenoid, and Aryteno-epiglottidean muscles.

The morsel of food after leaving the tongue passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance; then the Palato-glossi muscles, the constrictors of the fauces, contract behind the food; the soft palate is slightly raised by the Levator palati, and made tense by the Tensor palati; and the Palato-pharyngei, by their contraction, pull the pharynx upward over the morsel of food, and at the same time come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented passing into the upper part of the larynx or the posterior nares; at the same time the latter muscles form an inclined plane, directed obliquely downward and backward, along the under surface of which the morsel descends into the lower part of the pharynx. The Salpingo-pharyngeus raises the upper and lateral part of the pharynx—i.e., that part which is above the point where the Stylo-pharyngeus is attached to the pharynx.

Surgical Anatomy.—The muscles of the soft palate should be carefully dissected, the relations they bear to the surrounding parts especially examined, and their action attentively studied upon the dead subject, as the surgeon is required to divide one or more of these muscles in the operation of staphylorrhaphy. Sir W. Fergusson was the first to show that in the congenital deficiency called cleft palate the edges of the fissure are forcibly separated by the action of the Levatores palati and Palato-pharyngei muscles, producing very considerable impediment to the healing process after the performance of the operation for uniting their margins by adhesion; he consequently recommended the division of these muscles as one of the most important steps in the operation. This he effected by an incision made with a curved knife introduced behind the soft palate. The incision is to be half-way between the hamular process and Eustachian tube and perpendicular to a line drawn between them. This incision perfectly accomplishes the division of the Levator palati. The Palato-pharyngeus may be divided by cutting across the posterior pillar of the soft palate, just below the tonsil, with a pair of blunt-pointed curved scissors; and the anterior pillar may be divided also. To divide the Levator palati the plan recommended by Mr. Pollock is to be greatly preferred. The soft palate being put upon the stretch, a double-edged knife is passed through it just on the inner side of the hamular process and above the line of the Levator palati. The handle being now alternately raised and depressed, a sweeping cut is made along the posterior surface of the soft palate, and the knife withdrawn, leaving only a small opening in the mucous membrane on the anterior surface. If this operation is performed on the dead body and the parts afterward dissected, the Levator palati will be found completely divided. In the present day, however, this division of the muscles, as part of the operation of staphylorrhaphy, is not so much insisted upon. All tension is prevented by making longitudinal incisions on either side, parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

7. The Anterior Vertebral Region (Fig. 279).

Rectus capitis anticus major. Rectus capitis lateralis.
Rectus capitis anticus minor. Longus colli.

The Rectus Capitis Anticus Major or the Longus Capitis, broad and thick above, narrow below, appears like a continuation upward of the Sca-

1 We now know that normal deglutition can be carried out when the epiglottis is so small that it cannot cover the opening into the larynx, or when it has been removed surgically. In such cases the sphincter muscles which surround the laryngeal aperture contract during swallowing and prevent the entrance of foreign bodies into the larynx.—Ed.
lenus anticus. It arises by four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and ascends, converging toward its fellow of the opposite side, to be inserted into the basilar process of the occipital bone.

Relations.—By its anterior surface, with the pharynx, the sympathetic nerve, and the sheath enclosing the internal and common carotid artery, internal jugular vein, and pneumogastric nerve; by its posterior surface, with the Longus colli, the Rectus capitis anticus minor, and the upper cervical vertebrae.

The **Rectus Capitis Anticus Minor** is a short, flat muscle, situated immediately behind the upper part of the preceding. It arises from the anterior surface of the lateral mass of the atlas and from the root of its transverse process, and, passing obliquely upward and inward, is inserted into the basilar process immediately behind the preceding muscle.

Relations.—By its anterior surface, with the Rectus capitis anticus major; by its posterior surface, with the front of the occipito-atlantal articulation.

The **Rectus Capitis Lateralis** is a short, flat muscle, which arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

Relations.—By its anterior surface, with the internal jugular vein; by its posterior surface, with the vertebral artery. On its outer side lies the occipital artery; on its inner side, the suboccipital nerve.

The **Longus Colli** is a long, flat muscle, situated on the anterior surface of the spine, between the atlas and the third dorsal vertebra. It is broad in the middle,
narrow and pointed at each extremity, and consists of three portions: a superior oblique, an inferior oblique, and a vertical portion. The superior oblique portion arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae, and, ascending obliquely inward, is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The inferior oblique portion, the smallest part of the muscle, arises from the front of the bodies of the first two or three dorsal vertebrae, and, ascending obliquely outward, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The vertical portion lies directly on the front of the spine; it arises, below, from the front of the bodies of the upper three dorsal and lower three cervical vertebrae, and is inserted above into the front of the bodies of the second, third, and fourth cervical vertebrae.

Relations.—By its anterior surface, with the prevertebral fascia, the pharynx, the oesophagus, sympathetic nerve, the sheath of the great vessels of the neck, the inferior thyroid artery, and recurrent laryngeal nerve; by its posterior surface, with the cervical and dorsal portions of the spine. Its inner border is separated from the opposite muscle by a considerable interval below, but they approach each other above.

8. The Lateral Vertebral Region (Figs. 279, 280).

The Scalenus Anticus (m. scalenus anterior) is a conical-shaped muscle, situated deeply at the side of the neck, behind the Sterno-mastoid. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and, descending almost vertically, is inserted by a narrow, flat tendon into the Scalenic tubercle on the inner border and upper surface of the first rib. The lower part of this muscle separates the subclavian artery and vein, the latter being in front, and the former, with the brachial plexus, behind.

 Relations.—In front, with the clavicle, the Subclavius, Sterno-mastoid, and Omo-hyoid muscles, the Transversalis colli, the suprascapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve; by its posterior surface, with the Scalenus medius, pleura, subclavian artery, and brachial plexus of nerves. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebrae, between the attachments of the Scalenus anticus and Longus colli, lies the ascending cervical branch of the inferior thyroid artery.

The Scalenus Medius, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebrae,
and, descending along the side of the vertebral column, is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the Scalene anticus by the subclavian artery below and the cervical nerves above. The posterior thoracic, or nerve of Bell, is formed in the substance of the Scalenus medius and emerges from it. The nerve to the Rhomboids also pierces it.

Relations.—By its anterior surface, with the Sterno-mastoid; it is crossed by the clavicle, the Omo-hyoid muscle, subclavian artery, and cervical nerves. To its outer side is the Levator anguli scapule and the Scalenus posticus muscle.

The Scalenum Posticus (m. scalenus posterior), the smallest of the three Scaleni, arises, by two or three separate tendons, from the posterior tuberces of the transverse processes of the lower two or three cervical vertebrae, and, diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus magnus. This is the most deeply placed of the three Scaleni, and is occasionally blended with the Scalenus medius.

Nerves.—The Rectus capitis anticus major and minor and the Rectus lateralis are supplied by the first cervical nerve, and from the loop formed between it and the second; the Longus colli and Scaleni, by branches from the anterior divisions of the lower cervical nerves (fifth, sixth, seventh, and eighth) before they form the brachial plexus. The Scalenum medius also receives a filament from the deep external branches of the cervical plexus.

Actions.—The Rectus anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backward. These muscles also serve to flex the head, and, from their obliquity, rotate it, so as to turn the face to one or the other side. The Longus colli flexes and slightly rotates the cervical portion of the spine. The Scaleni muscles, when they take their fixed point from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed point from below, they bend the spinal column to one or the other side. If the muscles of both sides act, lateral movement is prevented, but the spine is slightly flexed. The Rectus lateralis, acting on one side, bends the head laterally.

Surface Form.—The muscles in the neck, with the exception of the Platysma myoides, are invested by the deep cervical fascia, which softens down their form, and is of considerable importance in connection with deep cervical abscesses and tumors, modifying the direction of the growth of tumors and of the enlargement of abscesses, and causing them to extend laterally instead of toward the surface. The Platysma myoides does not influence surface form except when in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. Sometimes this contraction takes place suddenly and repeatedly as a sort of spasmodic twitching, the result of a nervous habit. The Sterno-cleido-mastoid is the most important muscle of the neck as regards its surface form. If the muscle is put into action by drawing the chin downward and to the opposite shoulder, its surface form will be plainly outlined. The spinal origin will stand out as a sharply-defined ridge, while the clavicular origin will present a flatter and not so prominent an outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick rounded anterior border gradually becoming less marked above. On the opposite side—i. e., on the side to which the head is turned—the outline is lost, its place being occupied by an oblique groove in the integument. When the muscle is at rest its anterior border is still visible, forming an oblique rounded ridge, terminating below in the sharp outline of the sternal head. The posterior border of the muscle does not show above the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sterno-clavicular joint. It is an important surface-marking in the operation of ligature of the common carotid artery and in some other operations. Between the sternal and clavicular heads is a slight depression, most marked when the muscle is in action. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped space, the suprasternal notch, more pronounced below, and becoming toned down above, where the Sterno-hyoid and Sterno-thyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the Digastric to a certain extent influences surface form. It corresponds to a line drawn from the symphysis of the lower jaw to
the side of the body of the hyoid bone, and renders this part of the hyo-mental region convex. In the posterior triangle of the neck, the posterior belly of the Omni-hyoid, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

**MUSCLES AND FASCIAE OF THE TRUNK.**

The muscles of the Trunk may be arranged in four groups, corresponding with the region in which they are situated.

I. The Back.  
II. The Thorax.  
III. The Abdomen.  
IV. The Perineum.

**I. MUSCLES OF THE BACK.**

The muscles of the Back are very numerous, and may be subdivided into five layers:

**FIRST LAYER.**

Trapezius.  
Latissimus dorsi.

**SECOND LAYER.**

Levator anguli scapulae.  
Rhomboideus minor.  
Rhomboideus major.

**THIRD LAYER.**

Serratus posticus superior.  
Serratus posticus inferior.  
Splenius capitis.  
Splenius colli.

**FOURTH LAYER.**

Sacroiliac and Lumbar Regions.  
Erector spinae.

Dorsal Region.

Ilio-costalis.  
Musculus accessorius ad ilio-costalem.

**The First Layer (Fig. 282).**

Dissection (Fig. 281).—Place the body in a prone position, with the arms extended over the sides of the table, and the chest and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to the mastoid process, and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last dorsal vertebra, upward and outward, to the acromion process. This incision corresponds with the lower border of the Trapezius muscle. The flaps of integument are then to be removed in the direction shown in the figure.
Superficial Fascia.—The superficial fascia is exposed upon removing the skin from the back. It forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the superficial fascia in other parts of the body.

Deep Fascia.—The deep fascia is a dense fibrous layer attached to the occipital bone, the spines of the vertebrae, the crest of the ilium, and the spine of the scapula. It covers the superficial muscles, forming sheaths for them, and in the neck forms the posterior part of the deep cervical fascia; in the thorax it is continuous with the deep fascia of the axilla and chest, and in the abdomen with that covering the abdominal muscles. In the back of the thoracic region the deep fascia is called the vertebral aponeurosis or the aponeurosis of the latissimus dorsi muscle. It covers the erector spine muscles, and is the posterior layer of the lumbar fascia.

The Trapezius is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. It arises from the external occipital protuberance and the inner third of the superior curved line of the occipital bone; from the ligamentum nuchae, the spinous process of the seventh cervical, and the spinous processes of all the dorsal vertebrae; and from the corresponding portion of the supraspinous ligament. From this origin the superior fibres proceed downward and outward, the inferior ones upward and outward, and the middle fibres horizontally, and are inserted, the superior ones into the outer third of the posterior border of the clavicle; the middle fibres into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in a triangular aponeurosis, which glides over a smooth surface at the inner extremity of the spine, to be inserted into a tubercle at the outer part of this smooth surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin and insertion. At its occipital origin it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance of aponeuroses. At its origin from the spines of the vertebrae it is connected to the bones by means of a broad semi-elliptical aponeurosis, which occupies the space between the sixth cervical and the third dorsal vertebrae, and forms, with the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle arises by numerous short tendinous fibres. If the Trapezius is dissected on both sides, the two muscles resemble a trapezium or diamond-shaped quadrangle; two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the last dorsal vertebra. The clavicular insertion of this muscle varies as to the extent of its attachment; it sometimes advances as far as the middle of the clavicle, and may even become blended with the posterior edge of the Sterno-mastoid or overlap it. This should be borne in mind in the operation for tying the third part of the subclavian artery.

Fig. 281.—Dissection of the muscles of the back.
Fig. 282.—Muscles of the back. On the left side is exposed the first layer; on the right side, the second layer and part of the third.
Relations.—By its superficial surface, with the integument; by its deep surface, in the neck, with the Complexus, Splenius, Levator anguli scapulae, and Rhomboideus minor; in the back, with the Rhomboideus major, Supraspinatus, Infraspinatus, and Vertebral aponeurosis (which separates it from the prolongations of the Erector spinae), and the Latissimus dorsi. The spinal accessory nerve and the superficial cervical artery and branches from the third and fourth cervical nerves pass beneath the anterior border of this muscle. The anterior margin of its cervical portion forms the posterior boundary of the posterior triangle of the neck, the other boundaries being the Sterno-mastoid in front and the clavicle below.

The Ligamentum nuchae (Fig. 282) is a fibrous membrane, which, in the neck, represents the supraspinous and interspinous ligaments of the lower vertebrae. It extends from the external occipital protuberance to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina (fascia nuchae) is given off, which is attached to the external occipital crest, the posterior tubercle of the atlas, and the spinous process of each of the cervical vertebrae, so as to form a septum between the muscles on each side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The Latissimus Dorsi is a broad flat muscle, which covers the lumbar and the lower half of the dorsal regions, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. It arises by tendinous fibres from the spinous processes of the six inferior dorsal vertebrae and from the posterior layer of the lumbar fascia (see page 416), by which it is attached to the spines of the lumbar and sacral vertebrae and to the supraspinous ligament. It also arises from the external lip of the crest of the ilium, behind the origin of the External oblique, and by fleshy digitations from the three or four lower ribs, which are interposed between similar processes of the External oblique muscle (Fig. 289, page 434). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upward, and the lower vertically upward, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and occasionally receives a few fibres of origin from it. The muscle then curves around the lower border of the Teres major, and is twisted upon itself so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It then terminates in a short quadrilateral tendon, about three inches in length, which, passing in front of the tendon of the Teres major, is inserted into the bottom of the bicipital groove of the humerus, its insertion extending higher on the humerus than that of the tendon of the Pectoralis major. The lower border of the tendon of this muscle is united with that of the Teres major, the surfaces of the two being separated by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. This muscle at its insertion gives off an expansion to the deep fascia of the arm.

A muscular slip, the axillary arch, varying from 3 to 4 inches in length, and from ½ to ¾ of an inch in breadth, occasionally arises from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coraco-brachialis, or the fascia over the Biceps. The position of this abnormal slip is a point of interest in its relation to the axillary artery, as it crosses the vessel just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It may be easily recognized by the transverse direction of its fibres. Dr. Struther found it, in 8 out of 105 subjects, occurring seven times on both sides. In most subjects there is a fibrous axillary arch, in only a few is the arch muscular.

There is usually a fibrous slip which passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps. This is occasionally muscular, and is the representative of the Dorsa-epitrochlearis muscle of apes.
Relations.—Its superficial surface is subcutaneous, excepting at its upper part, where it is covered by the Trapezius, and at its insertion, where its tendon is crossed by the axillary vessels and the brachial plexus of nerves. By its deep surface it is in relation with the lumbar fascia, the Serratus posticus inferior, the lower External intercostal muscles and ribs, inferior angle of the scapula, Rhomboideus major, Infraspinatus, and Teres major. Its outer margin is separated below from the External oblique by a small triangular interval, the triangle of Petit (trigonum lumbale [Petiti]); and another triangular interval exists between its upper border and the margin of the Trapezius, in which the Rhomboideus major muscle is exposed.

Nerves.—The Trapezius is supplied by the spinal accessory, and by branches from the anterior divisions of the third and fourth cervical nerves: the Latissimus dorsi, by the middle or long subscapular nerve.

The Second Layer (Fig. 282).

Dissection.—The Trapezius must be removed, in order to expose the next layer; to effect this, detach the muscle from its attachment to the clavicle and spine of the scapula, and turn it back toward the spine.

The Levator Anguli Scapulae (m. levator scapulae) is situated at the back part and side of the neck. It arises by tendinous slips from the transverse process of the atlas, and from the posterior tubercles of the transverse processes of the second, third, and fourth cervical vertebrae; these, becoming fleshy, are united so as to form a flat muscle, which, passing downward and backward, is inserted into the posterior border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine.

Relations.—By its superficial surface, with the integument, Trapezius, and Sterno-mastoid; by its deep surface, with the Splenius colli, Transversalis cervicis, Cervicalis ascendens, and Serratus posticus superior muscles, and with the posterior scapular artery and the nerve to the Rhomboids.

The Rhomboideus Minor arises from the ligamentum nuchae and spinous processes of the seventh cervical and first dorsal vertebrae. Passing downward and outward, it is inserted into the margin of the triangular smooth surface at the root of the spine of the scapula. This small muscle is usually separated from the Rhomboideus major by a slight cellular interval.

Relations.—By its superficial (posterior) surface, with the Trapezius; by its deep (anterior) surface, with the same structures as the Rhomboideus major.

The Rhomboideus Major is situated immediately below the preceding, the adjacent margins of the two being occasionally united. It arises by tendinous fibres from the spinous processes of the four or five upper dorsal vertebrae and the supraspinous ligament, and is inserted into a narrow tendinous arch attached above to the lower part of the triangular surface at the root of the spine; below, to the inferior angle, the arch being connected to the border of the scapula by a thin membrane. When the arch extends, as it occasionally does, but a short distance, the muscular fibres are inserted into the scapula itself.

Relations.—By its superficial (posterior) surface, with the Trapezius and Latissimus dorsi; by its deep (anterior) surface, with the Serratus posticus superior, posterior scapular artery, the vertebral aponeurosis which separates it from the prolongations from the Erector spine, the Intercostal muscles, and ribs.

Nerves.—The Rhomboid muscles are supplied by branches from the anterior division of the fifth cervical nerve; the Levator anguli scapulae, by the anterior
divisions of the third and fourth cervical nerves, and frequently by a branch from the nerve to the Rhomboids.

**Actions.**—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachment. The whole of the Trapezius when in action retracts the scapula and braces back the shoulder; if the head is fixed, the upper part of the Trapezius will elevate the point of the shoulder, as in supporting weights; when the lower fibres are brought into action, they assist in depressing the bone. The middle and lower fibres of the muscle rotate the scapula, causing elevation of the acromion process. If the shoulders are fixed, both Trapezi, acting together, will draw the head directly backward; or if only one acts the head is drawn to the corresponding side. The Latissimus dorsi, when it acts upon the humerus, depresses it, draws it backward, adducts, and at the same time rotates it inward. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm is fixed, the muscle may act in various ways upon the trunk; thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms are fixed, the two muscles may assist the Abdominal and great Pectoral muscles in suspending and drawing the whole trunk forward, as in climbing or walking on crutches. The Levator anguli scapulae raises the superior angle of the scapula, and by so doing depresses the point of the shoulder. It assists the Trapezius in bearing weights and in shrugging the shoulders. If the shoulder be fixed, the Levator anguli scapulae inclines the neck to the corresponding side and rotates it in the same direction. The Rhomboid muscles carry the inferior angle backward and upward, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboides major acting especially on the lower angle of the scapula through the tendinous arch by which it is inserted. The Rhomboid muscles, acting together with the middle and inferior fibres of the Trapezius, will draw the scapula directly backward toward the spine.

**The Third Layer.**

Serratus posticus superior.

Serratus posticus inferior.

Splenius \{ Splenius capitis.

Splenius \{ Splenius colli.

**Dissection.**—To bring into view the third layer of muscles, remove the whole of the second, together with the Latissimus dorsi, by cutting through the Levator anguli scapulae and Rhomboid muscles near their origin, and reflecting them down ward, and by dividing the Latissimus dorsi in the middle by a vertical incision carried from its upper to its lower part, and reflecting the two halves of the muscle.

The **Serratus Posticus Superior** (m. serratus posterior superior) is a thin, flat, quadrilateral muscle situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the ligamentum nuchae, and from the spinous processes of the last cervical and two or three upper dorsal vertebrae and from the supraspinous ligament. Inclining downward and outward, it becomes muscular, and is inserted, by four fleshy digitations into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

**Relations.**—By its superficial surface, with the Trapezius, Rhomboidei, and Levator anguli scapulae; by its deep surface, with the Splenius and the vertebral aponeurosis, which separates it from the prolongations of the Erector spinae, and with the Intercostal muscles and ribs.

The **Serratus Posticus Inferior** (m. serratus posterior inferior) (Fig. 282) is situated at the junction of the dorsal and lumbar regions; it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a considerable interval. It arises by a thin aponeurosis from the spinous processes of the last two dorsal and two or three upper lumbar vertebrae, and from the supra-
spinous ligaments. Passing obliquely upward and outward, it becomes fleshy, and divides into four flat digitations, which are inserted into the lower borders of the four lower ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbar fascia.

**Relations.**—By its superficial surface, with the Latissimus dorsi. By its deep surface, with the Erector spinae, ribs, and Intercostal muscles. Its upper margin is continuous with the vertebral aponeurosis.

The **vertebral aponeurosis** is a thin, fibrous lamina, extending along the whole length of the back part of the thoracic region, serving to bind down the long Extensor muscles of the back which support the spine and head, and separate them from those muscles which connect the spine to the upper extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached in the median line to the spinous processes of the dorsal vertebrae; externally, to the angles of the ribs; and below, to the upper border of the Serratus posticus inferior and a portion of the lumbar fascia, which gives origin to the Latissimus dorsi; above, it passes beneath the Serratus posticus superior and the Splenius, and blends with the deep fascia of the neck.

The **lumbar fascia** or **aponeurosis** (Figs. 282 and 295), which may be regarded as the posterior aponeurosis of the Transversalis abdominis muscle, consists of three laminae, which are attached as follows: the *posterior layer*, to the spines of the lumbar and sacral vertebrae and their supraspinal ligaments; the *middle layer*, to the tips of the transverse processes of the lumbar vertebrae and their intertransverse ligaments; the *anterior layer*, to the roots of the lumbar transverse processes. The posterior layer is continued above as the vertebral aponeurosis, while inferiorly it is fixed to the outer lip of the iliac crest. With this layer are blended the aponeurotic origin of the Serratus posticus inferior and part of that of the Latissimus dorsi. The middle layer is attached above to the last rib, and below to the iliac crest; the anterior layer is fixed below to the ilio-lumbar ligament and iliac crest; while above it is thickened to form the external arcuate ligament of the Diaphragm, and stretches from the tip of the last rib to the transverse process of the first or second lumbar vertebra. These three layers, together with the vertebral column, enclose two spaces, the posterior of which is occupied by the Erector spinae muscle, and the anterior by the Quadratus lumborum.

Now detach the Serratus posticus superior from its origin, and turn it outward, when the Splenius muscle will be brought into view.

The **Splenius** (Fig. 282) is situated at the back of the neck and upper part of the dorsal region. At its origin it is a single muscle, which soon after its origin becomes broad, and divides into two portions, which have separate insertions. It arises, by tendinous fibres, from the lower half of the ligamentum nuchae; from the spinous processes of the last cervical and of the six upper dorsal vertebrae; and from the supraspinal ligament. From this origin the fleshy fibres proceed obliquely upward and outward, forming a broad flat muscle, which divides as it ascends into two portions, the **Splenius capitis** and **Splenius colli**.

The **Splenius capitis** (*m. splenius capitis*) is inserted into the mastoid process of the temporal bone, and into the rough surface on the occipital bone just beneath the superior curved line.

The **Splenius colli** (*m. splenius cervicis*) is inserted, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the two or three upper cervical vertebrae.

The Splenius is separated from its fellow of the opposite side by a triangular interval, in which is seen the Complexus.

**Relations.**—By its superficial surface, with the Trapezius, from which it is separated below by the Rhomboidei and the Serratus posticus superior. It is covered
at its insertion by the Sterno-mastoid, and at the lower and back part of the neck by the Levator anguli scapulae; by its deep surface, with the Spinalis dorsi, Longissimus dorsi, Semispinalis colli, Complexus, Trachelo-mastoid, and Transversalis cervicis.

**Nerves.**—The Splenius is supplied from the external branches of the posterior divisions of the cervical nerves; the Serratus posterior superior is supplied by the external branches of the posterior divisions of the upper dorsal nerves; the Serratus posterior inferior by the external branches of the posterior divisions of the lower dorsal nerves.

**Actions.**—The Serrati are respiratory muscles. The Serratus posterior superior elevates the ribs; it is therefore an inspiratory muscle; while the Serratus inferior draws the lower ribs downward and backward, and thus elongates the thorax. It also fixes the lower ribs, thus aiding the downward action of the diaphragm and resisting the tendency which it has to draw the lower ribs upward and forward. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral aponeurosis. The Splenii muscles of the two sides, acting together, draw the head directly backward, assisting the Trapezius and Complexus; acting separately, they draw the head to one or the other side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

**The Fourth Layer** (Fig. 283).

I. Erector spinae.

- **a. Outer Column.**
  - Ilio-costalis.
  - Musculus accessorius.
  - Cervicalis ascendens.

- **b. Middle Column.**
  - Longissimus dorsi.
  - Transversalis cervicis.
  - Trachelo-mastoid.

- **c. Inner Column.**
  - Spinalis dorsi.
  - Spinalis colli.

II. Complexus.

**Dissection.**—To expose the muscles of the fourth layer, remove entirely the Serrati and the vertebral and lumbar fasciae. Then detach the Splenius by separating its attachment to the spinous processes and reflecting it outward.

The **Erector Spinae** (*m. sacrospinalis*) and its prolongations in the dorsal and cervical regions fill up the vertebral groove on each side of the spine. It is covered in the lumbar region by the lumbar fascia; in the dorsal region, by the Serrati muscles and the vertebral aponeurosis; and in the cervical region, by a layer of cervical fascia continued beneath the Trapezius and the Splenius. This large muscular and tendinous mass varies in size and structure at different parts of the spine. In the sacral region the Erector spine is narrow and pointed, and its origin chiefly tendinous in structure. In the lumbar region the muscle becomes enlarged, and forms a large fleshy mass. In the dorsal region it subdivides into two parts, which gradually diminish in size as they ascend to be inserted into the vertebrae and ribs.

The Erector spine arises from the anterior surface of a very broad and thick tendon, which is attached, internally, to the spines of the sacrum, to the spinous processes of the lumbar and the eleventh and twelfth dorsal vertebrae, and the supraspinous ligament; externally, to the back part of the inner lip of the crest of the ilium, and to the series of eminences on the posterior part of the sacrum, which represents the transverse processes, where it blends with the great sacro-sciatic and posterior sacro-iliac ligaments. Some of its fibres are continuous with the fibres
Fig. 283.—Muscles of the back. Deep layers.
of origin of the Gluteus maximus. The muscular fibres form a single large fleshy mass, bounded in front by the transverse processes of the lumbar vertebrae and by the middle lamella of the lumbar fascia. Opposite the last rib it divides into two parts, the Ilio-costalis and the Longissimus dorsi; the Spinalis dorsi is given off from the latter in the upper dorsal region.

The Ilio-costalis or Sacro-lumbal (m. iliocostalis lumborum), the external portion of the Erector spine, is inserted, generally, by six or seven flattened tendons into the inferior borders of the angles of the six or seven lower ribs. The number of the tendons of this muscle is, however, very variable, and therefore the number of ribs into which it is inserted vary. Frequently it is found to possess nine or ten tendons, and sometimes as many tendons as there are ribs, and is then inserted into the angles of all the ribs. If this muscle is reflected outward, it will be seen to be reinforced by a series of muscular slips which arise from the angles of the ribs; by means of these the Ilio-costalis is continued upward to the upper ribs and cervical portion of the spine. The accessory portions form two additional muscles, the Musculus accessorius and the Cervicalis ascendens.

The Musculus accessorius ad ilio-costalem (m. iliocostalis dorsi) arises, by separate flattened tendons, from the upper borders of the angles of the six lower ribs; these become muscular, and are finally inserted, by separate tendons, into the upper borders of the angles of the six upper ribs and into the back of the transverse processes of the seventh cervical vertebra.

The Cervicalis ascendens (m. iliocostalis cervicis) is the continuation of the Accessorius upward into the neck; it is situated on the inner side of the tendons of the Accessorius, arising from the angles of the four or five upper ribs, and is inserted by a series of slender tendons into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebrae.

The Longissimus dorsi is the middle and largest portion of the Erector spine. In the lumbar region, where it is as yet blended with the Ilio-costalis, some of the fibres are attached to the whole length of the posterior surface of the transverse processes and the accessory processes of the lumbar vertebrae, and to the middle layer of the lumbar fascia. In the dorsal region, the Longissimus dorsi is inserted, by long thin tendons, into the tips of the transverse processes of all the dorsal vertebrae, and into from seven to eleven of the lower ribs between their tubercles and angles. This muscle is continued upward to the cranium and cervical portion of the spine by means of two additional muscles, the Transversalis cervicis and Trachelo-mastoid.

The Transversalis cervicis or Transversalis colli (m. longissimus cervicis), placed on the inner side of the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the six upper dorsal vertebrae, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebrae, from the second to the sixth inclusive.

The Trachelo-mastoid (m. longissimus capitis) lies on the inner side of the preceding, between it and the Complexus muscle. It arises, by tendons, from the transverse processes of the five or six upper dorsal vertebrae, and the articular processes of the three or four lower cervical. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the mastoid process, beneath the Splenius and Sterno-mastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.

The Spinalis dorsi connects the spinous processes of the upper lumbar and the dorsal vertebrae together by a series of muscular and tendinous slips which are

---

1 This muscle is sometimes called "Cervicalis descendens." The student should remember that these long muscles take their fixed point from above or from below, according to circumstances.

2 These two muscles (Transversalis cervicis and Trachelo-mastoid) are sometimes described as one, having a common origin, but dividing above at their insertion. The Trachelo-mastoid is then termed the Transversalis capitis.
THE MUSCLES AND FASCIÆ

intimately blended with the Longissimus dorsi. It is situated at the inner side of the Longissimus dorsi, arising, by three or four tendons, from the spinous processes of the first two lumbar and the last two dorsal vertebrae: these, uniting, form a small muscle, which is inserted, by separate tendons, into spinous processes of the dorsal vertebrae, the number varying from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The Spinalis colli (m. spinalis cervicis) is a small muscle, connecting together the spinous processes of the cervical vertebrae, and analogous to the Spinalis dorsi in the dorsal region. It varies considerably in its size and in its extent of attachment to the vertebrae, not only in different bodies, but on the two sides of the same body. It usually arises by fleshy or tendinous slips, varying from two to four in number, from the spinous processes of the fifth, sixth, and seventh cervical vertebrae, and occasionally from the first and second dorsal, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebrae below it. This muscle was found absent in five cases out of twenty-four.

**Relations.**—The Erector spinae and its prolongations are bound down to the vertebrae and ribs in the lumbar and dorsal regions by the lumbar fascia and the vertebral aponeurosis. The inner part of these muscles covers the muscles of the fifth layer. In the neck they are in relation, by their superficial surface, with the Trapezius and Splenius; by their deep surface, with the Semispinalis dorsi et colli and the Recti and Obliqui.

The Complexus (m. semispinalis capitis) is a broad thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis cervicis and Trachelo-mastoid. It arises, by a series of tendons, from the tips of the transverse processes of the upper six or seven dorsal and the last cervical vertebrae, and from the articular processes of the three cervical above this. The tendons, uniting, form a broad muscle, which passes obliquely upward and inward, and is inserted into the innermost depression between the two curved lines of the occipital bone. This muscle, about its middle, is traversed by a transverse tendinous intersection. The biventer cervicis is a small fasciculus, situated on the inner side of the preceding, and in the majority of cases blended with it; it has received its name from having a tendon intervening between two fleshy bellies. It is sometimes described as a part of the Complexus. It arises by from two to four tendinous slips, from the transverse processes of as many of the upper dorsal vertebrae, and is inserted, on the inner side of the Complexus, into the superior curved line of the occipital bone.

**Relations.**—The Complexus is covered by the Splenius and the Trapezius. It lies on the Rectus capitis posticus major and minor, the Obliquus capitis superior and inferior, and on the Semispinalis colli, from which it is separated by the profundâ cervicis artery, the princeps cervicis artery, and branches of the posterior primary divisions of the cervical nerves. The Biventer cervicis is separated from its fellow of the opposite side by the ligamentum nuchae.

**Dissection.**—Remove the muscles of the preceding layer by dividing and turning aside the Complexus; then detach the Spinalis and Longissimus dorsi from their attachments, divide the Erector spinae at its connection below to the sacral and lumbar spines and turn it outward. The muscles filling up the interval between the spinous and transverse processes are then exposed.
The **Semispinalis Dorsi** consists of thin, narrow, fleshy fasciculi interposed between tendons of considerable length. It *arises* by a series of small tendons from the transverse processes of the lower dorsal vertebrae, from the tenth or eleventh to the fifth or sixth; and is *inserted*, by five or six tendons, into the spinous processes of the upper four dorsal and lower two cervical vertebrae.

The **Semispinalis Colli** (*m. semispinalis cervicis*), thicker than the preceding, *arises* by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six dorsal vertebrae, and is *inserted* into the spinous processes of four cervical vertebrae, from the axis to the fifth cervical. The fasciculus connected with the axis is the largest, and chiefly muscular in structure.

**Relations.**—By their *superficial surface*, from below upward, with the Spinalis dorsi, Longissimus dorsi, Splenius, Complexus, the profunda cervicis artery, the princeps cervicis artery, and the internal branches of the posterior divisions of the first, second, and third cervical nerves; by their *deep surface*, with the Multifidus spinae.

The **Multifidus Spinae** (*m. multifidus*) consists of a number of fleshy and tendinous fasciculi which fill up the groove on either side of the spinous processes of the vertebrae, from the sacrum to the axis. In the sacral region these fasciculi *arise* from the back of the sacrum, as low as the fourth sacral foramen, and from the aponeurosis of origin of the Erector spinae; from the inner surface of the posterior superior spine of the ilium and posterior sacro-iliac ligaments; in the lumbar regions, from the articular processes; in the dorsal region, from the transverse processes; and in the cervical region, from the articular processes of the three or four lower vertebrae. Each fasciculus, passing obliquely upward and inward, is *inserted* into the whole length of the spinous process of one of the vertebrae above. These fasciculi vary in length: the most superficial, the longest, pass from one vertebra to the third or fourth above; those next in order pass from one vertebra to the second or third above; whilst the deepest connect two contiguous vertebrae.

**Relations.**—By its *superficial surface*, with the Longissimus dorsi, Spinalis dorsi, Semispinalis dorsi, and Semispinalis colli; by its *deep surface*, with the laminae and spinous processes of the vertebrae, and with the Rotatores spine in the dorsal region.

The **Rotatores Spinae** (*mm. rotatores*) are found only in the dorsal region of the spine, beneath the Multifidus spinae; they are eleven in number on each side. Each muscle is small and somewhat quadrilateral in form; it *arises* from the upper and back part of the transverse process, and is *inserted* into the lower border and outer surface of the lamina of the vertebra above, the fibres extending as far inward as the root of the spinous process. The first is found between the first and second dorsal; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The **Supraspinales** consist of a series of fleshy bands which lie on the spinous processes in the cervical region of the spine.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebrae, one on each side of the interspinous ligament. In the **cervical region** they are most distinct, and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the last cervical and the first dorsal. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the **dorsal region** they are found between the first and second vertebrae, and occasionally between the second and third; and below, between the eleventh and twelfth. In the **lumbar region** there are four pairs of these muscles in the intervals between the five lumbar vertebrae. There is also occasionally one in the interspinous space, between the last dorsal and first lumbar, and between the fifth lumbar and the sacrum.
The **Extensor Coccygis** is a slender muscular fasciculus, occasionally present, which extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last bone of the sacrum or first piece of the coccyx, and passes downward to be inserted into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebrae of the lower animals.

The **Intertransversales (mm. intertransversarii)** are small muscles placed between the transverse processes of the vertebrae. In the **cervical region** they are most developed, consisting of rounded muscular and tendinous fasciculi, which are placed in pairs, passing between the anterior and the posterior tubercles of the transverse processes of two contiguous vertebrae, separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. In this region there are seven pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first dorsal vertebrae. In the **dorsal region** they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper dorsal vertebrae; but between the transverse processes of the lower three dorsai vertebrae, and between the transverse processes of the last dorsal and the first lumbar, they are muscular in structure. In the **lumbar region** they are arranged in pairs, on either side of the spine, one set occupying the entire interspace between the transverse processes of the lumbar vertebrae, the **intertransversales laterales (mm. intertransversarii laterales)**; the other set, **intertransversales mediales (mm. intertransversarii mediales)**, passing from the accessory process of one vertebra to the mammillary process of the next.

The **Rectus Capitis Posticus Major (m. rectus capitis posterior major)** arises by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upward and outward, they leave between them a triangular space, in which are seen the Recti capitis postici minores muscles.

**Relations.**—By its **superficial surface**, with the Complexus, and, at its insertion, with the Superior oblique; by its **deep surface**, with part of the Rectus capitis posticus minor, the posterior arch of the atlas, the posterior occipito-atlantal ligament, and part of the occipital bone.

The **Rectus Capitis Posticus Minor (m. rectus capitis posterior minor)**, the smallest of the four muscles in this region, is of a triangular shape; it arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is inserted into the rough surface beneath the inferior curved line, nearly as far as the foramen magnum, nearer to the middle line than the preceding.

**Relations.**—By its **superficial surface**, with the Complexus and the Rectus capitis posticus major; by its **deep surface**, with the posterior occipito-atlantal ligament.

The **Obliquus Capitis Inferior**, the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes outward and slightly upward, to be inserted into the lower and back part of the transverse process of the atlas.

**Relations.**—By its **superficial surface**, with the Complexus and with the posterior division of the second cervical nerve, which crosses it; by its **deep surface**, with the vertebral artery and posterior atlanto-axial ligament.

The **Obliquus Capitis Superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding, and, passing obliquely upward and inward, is inserted into the occipital bone, between the two curved lines, external to the Complexus.
Relations.—By its superficial surface, with the Complexus and Trachelo-mastoid and occipital artery. By its deep surface, with the posterior occipito-atlantal ligament.

Between the two oblique muscles and the Rectus capitis posticus major a triangular interval exists, the suboccipital triangle. This triangle is bounded, above and internally, by the Rectus capitis posticus major; above and externally, by the Obliquus capitis superior; below and externally, by the Obliquus capitis inferior. It is covered in by a layer of dense fibro-fatty tissue, situated beneath the Complexus muscle. The floor is formed by the posterior occipito-atlantal ligament and the posterior arch of the atlas. It contains the vertebral artery, as it runs in a deep groove on the upper surface of the posterior arch of the atlas, and the posterior division of the suboccipital nerve.

Nerves.—The third, fourth, and fifth layers of the muscles of the back are supplied by the posterior primary divisions of the spinal nerves.

Actions.—When both the Spinales dorsi contract, they extend the dorsal region of the spine; when only one muscle contracts, it helps to bend the dorsal portion of the spine to one side. The Erector spinae, comprising the Ilio-costalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the spine in the erect posture; it also serves to bend the trunk backward when it is required to counterbalance the influence of any weight at the front of the body, as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distention, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the spine being drawn backward by the counterbalancing action of the Erector spinae muscles. The muscles which form the continuation of the Erector spinae upward steady the head and neck, and fix them in the upright position. If the Ilio-costalis and Longissimus dorsi of one side act, they serve to draw down the chest and spine to the corresponding side. The Cervicales ascendens, taking their fixed points from the cervical vertebrae, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversalis cervicis, when both muscles act, taking their fixed point from below, bend the neck backward. The Trachelomastoid, when both muscles act, taking their fixed point from below, bend the head backward; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti muscles draw the head backward. The Rectus capitis posticus major, owing to its obliquity, rotates the cranium, with the atlas, round the odontoid process, turning the face to the same side. The Multifidus spinee acts successively upon the different parts of the spine; thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the dorsal region, and so on throughout the entire length of the spine; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the spine preserves the erect posture without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The Multifidus spineæ, besides preserving the erect position of the spine, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the Obliquus externus abdominis. The Complexi draw the head directly backward: if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The Superior oblique draws the head backward, and, from the obliquity in the direction of its fibres, will slightly rotate the cranium, turning the face to the opposite side. The Obliquus capitis inferior rotates the atlas, and with it the cranium, round the odontoid process, turning the face to the same side. The Semispinales, when the muscles of the two sides act together, help to extend the
spine; when the muscles of one side only act, they rotate the dorsal and cervical parts of the spine, turning the body to the opposite side. The Supraspinales and Interspinales by approximating the spinous processes help to extend the spine. The Intertransversales approximate the transverse processes, and help to bend the spine to one side. The Rotatores spine assist the Multifidus spine to rotate the spine, so that the front of the trunk is turned to the side opposite to that from which the muscle acts.

Surface Forms.—The surface forms produced by the muscles of the back are numerous and difficult to analyze unless they are considered in systematic order. The most superficial layer, consisting of large strata of muscular substance, influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The Trapezius at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior border forms the posterior boundary of the posterior triangle of the neck. It forms a slight undulating ridge which passes downward and forward from the occiput to the junction of the middle and outer third of the clavicle. The tendinous ellipse formed by a part of the origin of the two muscles at the back of the neck is always to be seen as an oval depression, more marked when the muscle is in action. A slight dimple on the skin opposite the interval between the spinous processes of the third and fourth dorsal vertebra marks the triangular aponoeurosis by which the inferior fibres are inserted into the root of the spine of the scapula. From this point the inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth dorsal vertebra. In like manner the Latissimus dorsi softens down and modulates the underlying structures at the lower part of the back and lower part of the side of the chest. In this way it modulates the outline of the Erector spine; of the Serratus posticus inferior, which is sometimes to be discerned through it, and is sometimes entirely obscured by it; of part of the Serratus magnus and Superior oblique, which it covers; and of the convex oblique ridges formed by the ribs with the intervening intercostal spaces. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forward and upward to the posterior border of the axilla, where it combines with the Teres major in forming a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The Levator anguli scapulae reveals itself as a prominent divergent line, running downward and outward, from the transverse processes of the upper cervical vertebrae to the angle of the scapula, covered over and toned down by the overlying Trapezius. The Rhomboidei produce, when in action, a vertical eminence between the vertebral border of the scapula and the spinal furrow, varying in intensity according to the condition of contraction or relaxation of the Trapezius muscle, by which they are for the most part covered. The lowermost part of the Rhomboideus major is uncovered by the Trapezius, and forms on the surface an oblique ridge running upward and inward from the inferior angle of the scapula. Of the muscles of the third layer of the back, the Serratus posticus superior does not in any way influence surface form. The Serratus posticus inferior, when in strong action, may occasionally be revealed as an elevation beneath the Latissimus dorsi. The Spinae by their divergence serve to broaden out the upper part of the back of the neck and produce a local fulness in this situation, but do not otherwise influence surface form. Beneath all these muscles those of the fourth layer—the Erector spine and its continuations—influence the surface form in a decided manner. In the loins, the Erector spine, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the spinal furrow, and which below tapers to a point on the posterior surface of the sacrum and becomes lost there. In the back it forms a flattened plane which gradually becomes lost. In the neck the only part of this group of muscles which influences surface form is the Tracheo-mastoid, which produces a short convergent line across the upper part of the posterior triangle of the neck, appearing from under cover of the posterior border of the Sterno-mastoid and being lost below beneath the Trapezius.

II. MUSCLES AND FASCIAE OF THE THORAX.

The muscles belonging exclusively to this region are few in number. They are the

- Intercostales externi.
- Intercostales interni.
- Infracostales.
- Triangularis sterni.
- Levatores costarum.
- Diaphragm.

Intercostal Fascia.—A thin but firm layer of fascia covers the outer surface of the External intercostal and the inner surface of the Internal intercostal muscles;
and a third layer, more delicate, is interposed between the two planes of muscular fibres. These are the intercostal fasciae, external, middle, and internal; they are best marked in those situations where the muscular fibres are deficient, as between the External intercostal muscles and sternum, in front, and between the Internal intercostals and spine, behind.

The **Intercostal Muscles** (Figs. 291 and 315) are two thin planes of muscular and tendinous fibres, placed one over the other, filling up the intercostal spaces, and being directed obliquely between the margins of the adjacent ribs. They have received the name external and internal from the position they bear to one another. The tendinous fibres are longer and more numerous than the muscular; hence the walls of the intercostal spaces possess very considerable strength, to which the crossing of the muscular fibres materially contributes.

The **External Intercostals** (mm. intercostales externi) are eleven in number on each side. They extend from the tubercles of the ribs, behind, to the commencement of the cartilages of the ribs, in front, where they terminate in a thin membrane, the anterior intercostal membrane, which is continued forward to the sternum. They arise from the lower border of the rib above, and are inserted into the upper border of the rib below. In the two lowest spaces they extend to the ends of the cartilages, and in the upper two or three spaces they do not quite extend to the ends of the ribs. Their fibres are directed obliquely downward and forward, in a similar direction with those of the External oblique muscle of the abdomen. They are thicker than the Internal intercostals.

**Relations.**—By their outer surface, with the muscles which immediately invest the chest—viz., the Pectoralis major and minor, Serratus magnus, and Rhomboideus major, Serratus posticus superior and inferior, Scalenus posticus, Iliocostalis, Longissimus dorsi, Cervicalis ascendens, Transversalis cervicis, Levatores costarum, Obliquus externus abdominis, and the Latissimus dorsi; by their internal surface, with the middle intercostal fascia, which separates them from the intercostal vessels and nerve and the Internal intercostal muscles, and, behind, from the pleura.

The **Internal Intercostals** (mm. intercostales interni) are also eleven in number on each side. They commence anteriorly at the sternum in the interspaces between the cartilages of the true ribs, and from the anterior extremities of the cartilages of the false ribs, and extend backward as far as the angles of the ribs, whence they are continued to the vertebral column by a thin aponeurosis, the posterior intercostal membrane. They arise from the ridge on the inner surface of the rib above, as well as from the corresponding costal cartilage, and are inserted into the upper border of the rib below. Their fibres are directed obliquely downward and backward, passing in the opposite direction to the fibres of the External intercostal muscle.

**Relations.**—By their external surface, with the intercostal vessels and nerves and the External intercostal muscles; near the sternum, with the anterior intercostal membrane and the Pectoralis major. By their internal surface, with the pleura costalis, Triangularis sterni, and Diaphragm.

The **Infracostales** (mm. subcostales) consist of muscular and aponeurotic fasciculi, which vary in number and length; they are placed on the inner surface of the ribs, where the Internal intercostal muscles cease; they arise from the inner surface of one rib, and are inserted into the inner surface of the first, second, or third rib below. Their direction is most usually oblique, like the Internal intercostals. They are most frequent between the lower ribs.

The **Triangularis Sterni** (m. transversus thoracis) (Fig. 284) is a thin plane of muscular and tendinous fibres, situated upon the inner wall of the front of the chest. It arises from the lower third of the posterior surface of the sternum, from the posterior surface of the ensiform cartilage, and from the sternal ends of the costal
cartilages of the three or four lower true ribs. Its fibres diverge upward and outward, to be inserted by digitations into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis; those which succeed are oblique, whilst the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body.

Relations.—In front, with the sternum, ensiform cartilage, costal cartilages, internal intercostal muscles, and internal mammary vessels; behind, with the pleura, pericardium, and anterior mediastinum.

The Levatores Costarum (Fig. 283), twelve in number on each side, are small tendinous and fleshy bundles which arise from the extremities of the transverse processes of the seventh cervical and eleven upper dorsal vertebrae, and, passing obliquely downward and outward, are inserted into the upper border of the rib below them, between the tubercle and the angle. The Inferior levatores divide into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebrae.

Nerves.—The muscles of this group are supplied by the intercostal nerves.
The Diaphragm (diaphragma, from διάφραγμα, a partition wall) (Figs. 285, 286, and 287) is a thin, musculo-fibrous septum, consisting of muscular fibres externally, which arise from the circumference of the thoracic cavity and pass upward and inward to converge to a central tendon. It is placed obliquely at the junction of the upper with the middle third of the trunk, and separates the thorax from the abdomen, forming the floor of the former cavity and the roof of the latter. It is elliptical, its longest diameter being from side to side; is somewhat fan-shaped, the broad elliptical portion being horizontal, the narrow part, the crura, which represents the handle of the fan, vertical, and joined at right angles to the former. It is from this circumstance that some anatomists describe it as consisting of two portions, the upper or great muscle of the Diaphragm, and the lower or lesser muscle. It arises from the whole of the internal circumference of the thorax, being attached, in front, by fleshy fibres to the ensiform cartilage, external portion of the Diaphragm (pars sternalis); on either side, to the inner surface of the cartilages and bony portions of the six or seven inferior ribs, costal portion (pars costalis), interdigitating with the Transversalis; and behind, to two aponeurotic arches, named the ligamentum arcuatum externum and the ligamentum arcuatum internum, and by the crura, to the lumbar vertebrae, lumbar portion (pars lumbaris). The fibres from these sources vary in length: those arising from the ensiform appendix are very short and occasionally aponeurotic; those from the ligamenta arcuata, and more especially those from the cartilages of the ribs at the side of the chest, are longer, describe well-marked curves as they ascend, and finally converge to be inserted into the circumference of the central tendon. Between the sides of the muscular slip from the ensiform appendix and the cartilages of the adjoining ribs the fibres of the Diaphragm are deficient, the interval being filled by areolar tissue, covered on the thoracic side by the pleure; on the abdominal, by the peritoneum. This is, consequently, a weak point, and a portion of the contents of the abdomen may protrude through it into the chest, forming a phrenic or diaphragmatic hernia, or a collection of pus in the mediastinum may descend through it, so as to point at the epigastrium. A triangular gap is sometimes seen between the fibres springing from the internal and those arising from the external arcuate ligament. When it exists, the kidney is separated from the pleura only by fatty and areolar tissue.

A congenital deficiency in the Diaphragm may produce diaphragmatic hernia; in deficiency of the central tendon the hernia passes into the pericardial sac; in deficiency of one of the lateral portions the hernia passes into the pleural sac.

There are five arcuate ligaments, two internal, two external, and one middle.

The Ligamentum Arcuatum Internum (arcus lumbocostalis medialis) is a tendinous arch, thrown across the upper part of the Psoas magnus muscle, on each side of the spine. It is connected, by one end, to the outer side of the body of the first or second lumbar vertebra, being continuous with the outer side of the tendon of the corresponding crus; and, by the other end, to the front of the transverse process of the first, and sometimes also to that of the second, lumbar vertebra.

The Ligamentum Arcuatum Externum (arcus lumbocostalis lateralis) is the thickened upper margin of the anterior lamella of the lumbar fascia; it arches across the upper part of the Quadratus lumborum, being attached, by one extremity, to the front of the transverse process of the first lumbar vertebra, and, by the other, to the apex and lower margin of the last rib.

The arch of fibrous tissue which connects the crura of the diaphragm in front of the aorta is sometimes called the middle arcuate ligament. The Diaphragm is connected to the spine by two crura or pillars, which are situated on the bodies of lumbar vertebrae, on each side of the aorta. The crura, at their origin, are tendinous in structure; the right crus, larger and longer than the left, arising from the anterior common ligament and intervertebral substances of the three or four
THE MUSCLES AND FASCIAE

upper lumbar vertebrae; the left, from the two upper lumbar vertebrae. These tendinous portions of the crura pass forward and inward, and gradually con-

verge to meet in the middle line, forming an arch, beneath which passes the aorta, vena azygos major, and thoracic duct. From this tendinous arch muscular fibres arise, which diverge, the outermost portion being directed upward and

Fig. 285.—The Diaphragm, seen from above. (Poirier and Charpy.)

Fig. 286.—The Diaphragm, viewed from in front. (Testut.)
outward to the central tendon; the innermost decussating in front of the aorta and then diverging, so as to surround the oesophagus before ending in the central tendon. The fibres derived from the right crus are the most numerous and pass in front of those derived from the left. His and Spalteholz teach that three crura exist on each side—viz., the crus mediale, arising from the third and fourth lumbar vertebrae; the crus intermedium, from the second and third lumbar vertebrae; and the crus laterale, from the second or first lumbar vertebrae, and from the band of fascia which is stretched between the lateral part of the body of the first lumbar vertebra and the transverse process of the second lumbar vertebra in front of the Psoas muscle.

The Central or Cordiform Tendon of the Diaphragm (centrum tendineum) is a thin but strong tendinous aponeurosis, situated at the centre of the vault formed by the muscle, immediately below the pericardium, with which it is partly blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions, or leaflets, separated from one another by slight indentations. The right leaflet is the largest; the middle one, directed toward the ensiform cartilage, the next in size; and the left, the smallest. In structure, the tendon is composed of several planes of fibres which intersect one another at various angles, and unite into straight or curved bundles—an arrangement which affords it additional strength.

The Openings.—The openings connected with the Diaphragm are three large and several smaller apertures. The former are the aortic, the oesophageal, and the opening for the vena cava.

The Aortic Opening (hiatus aorticus) is the lowest and the most posterior of the three large apertures connected with this muscle, being at the level of the first lumbar vertebra. It is situated slightly to the left of the middle line, immediately in front of the bodies of the vertebrae; and is, therefore, behind the Diaphragm, not in it. It is an osseo-aponeurotic aperture, formed by a tendinous arch thrown across the front of the bodies of the vertebrae, from the crus on one side to that on the other, and transmits the aorta, vena azygos major, and thoracic duct. Sometimes the vena azygos major is transmitted upward through the right crus.
Occasionally some tendinous fibres are prolonged across the bodies of the vertebrae from the inner part of the lower end of the crura, passing behind the aorta, and thus converting the opening into a fibrous ring.

The Oesophageal Opening (hiatus oesophageus) is situated at the level of the tenth dorsal vertebra; it is elliptical in form, oblique in direction, muscular in structure, and, formed by the decussating fibres of the two crura, is placed above, and, at the same time, anterior, and a little to the left of the preceding. It transmits the oesophagus and pneumogastric nerves and some small oesophageal arteries. The anterior margin of this aperture is occasionally tendinous, being formed by the margin of the central tendon. The posterior and lateral margins are thick and the gullet is in contact with them for about half an inch. The right margin of the oesophageal opening is particularly prominent and lies in the oesophageal groove on the posterior surface of the left lobe of the liver.

The Opening for the Vena Cava or the Foramen Quadratum (foramen vena cavae) is the highest opening, being about on the level of the disk between the eighth and ninth dorsal vertebrae; it is quadrilateral in form, tendinous in structure, and placed at the junction of the right and middle leaflets of the central tendon, its margins being adherent to the wall of the inferior vena cava.

The right crus transmits the greater and lesser splanchnic nerves of the right side; the left crus transmits the greater and lesser splanchnic nerves of the left side, and the vena azygos minor. The gangliated cords of the sympathetic usually enter the abdominal cavity by passing behind the internal arcuate ligaments.

Serous Membranes.—The serous membranes in relation with the Diaphragm are four in number: three lining its upper or thoracic surface; one, its abdominal. The three serous membranes on its upper surface are the pleura on either side and the pericardium, which covers the middle portion of the tendinous centre. The serous membrane covering the under surface of the Diaphragm is a portion of the general peritoneal membrane of the abdominal cavity.

The Diaphragm is arched, being convex toward the chest and concave toward the abdomen. The right portion forms a complete arch from before backward, being accurately moulded over the convex surface of the liver, and having resting upon it the concave base of the right lung. The left portion is arched from before backward in a similar manner; but the arch is narrower in front, being encroached upon by the pericardium, and lower than the right, at its summit, by about three-quarters of an inch. It supports the base of the left lung, and covers the great end of the stomach, the spleen, and left kidney. At its circumference the Diaphragm is higher in the mesial line of the body than at either side; but in the middle of the thorax the central portion, which supports the heart, is on a lower level than the two lateral portions.

Nerves.—The Diaphragm is supplied by the phrenic nerves, the lower intercostal nerves and the phrenic plexus of the sympathetic.

Actions.—The Intercostals are the chief agents in the movement of the ribs in ordinary respiration. When the first rib is elevated and fixed by the Scaleni, the External intercostals raise the other ribs, especially their forepart, and so increase the capacity of the chest from before backward; at the same time they evert their lower borders, and so enlarge the thoracic cavity transversely. The Internal intercostals, at the side of the thorax, depress the ribs and invert their lower borders, and so diminish the thoracic cavity; but at the forepart of the chest these muscles assist the External intercostals in raising the cartilages.1 The Levatores

1 The view of the action of the Intercostal muscles given in the text is that which is taught by Hutchinson (Cyl. of Anat. and Phys., art. Thorax), and is usually adopted in our schools. It is, however, much disputed. Hamberger believed that the External intercostals act as elevators of the ribs, or muscles of inspiration, while the internal act in expiration. Haller taught that both sets of muscles act in common—viz., as muscles of inspiration—and this view is adopted by many of the best anatomists of the Continent, and appears sup-
costarum assist the External intercostals in raising the ribs. The Triangularis sterni draws down the costal cartilages; it is therefore an expiratory muscle.

The Diaphragm is the principal muscle of inspiration. When in a condition of rest the muscle presents a domed surface, concave toward the abdomen; and consists of a circumferential muscular and a central tendinous part. When the muscular fibres contract, they become less arched, or nearly straight, and thus cause the central tendon to descend, and in consequence the level of the chest-wall is lowered, the vertical diameter of the chest being proportionally increased. In this descent the different parts of the tendon move unequally. The left leaflet descends to the greatest extent; the right to a less extent, on account of the liver; and the central leaflet the least, because of its connection to the pericardium. In descending the Diaphragm presses on the abdominal viscera, and so to a certain extent causes a projection of the abdominal wall; but in consequence of these viscera not yielding completely, the central tendon becomes a fixed point, and enables the circumferential muscular fibres to act from it, and so elevate the lower ribs and expand the lower part of the thoracic cavity; and Duchenne has shown that the Diaphragm has the power of elevating the ribs, to which it is attached, by its contraction, if the abdominal viscera are in situ, but that if these organs are removed, this power is lost. When at the end of inspiration the Diaphragm relaxes, the thoracic walls return to their natural position in consequence of their elastic reaction and of the elasticity and weight of the displaced viscera.¹

In all expulsive acts the Diaphragm is called into action, to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, and crying, before vomiting, previous to the expulsion of the urine and feces, or of the fetus from the womb, a deep inspiration takes place.

The height of the Diaphragm is constantly varying during respiration, the muscle being carried upward or downward from the average level; its height also varies according to the degree of distention of the stomach and intestines, and the size of the liver. After a forced expiration, the right arch is on a level, in front, with the fourth costal cartilage; at the side, with the fifth, sixth, and seventh ribs; and behind, with the eighth rib, the left arch being usually from one to two ribs' breadth below the level of the right one. In a forced inspiration, it descends from one to two inches; its slope would then be represented by a line drawn from the ensiform cartilage toward the tenth rib. Prof. Wm. S. Forbes² is of the opinion that the Diaphragm is an appendage of the circulatory apparatus rather than the chief agent in respiration. He maintains that the opening in the vena cava is stationary and holds a constant relation to the ninth dorsal vertebra. He emphasizes the fact that the base of the pericardium is attached to the central tendon of the Diaphragm, and on the anterior and left side. The muscular fibres of the Diaphragm ascend upon and are attached to the pericardium. Prolongations of the fibrous pericardium pass upward as the pericardial ligaments. These ligaments form fibrous planes reaching from each side of the central tendon of the Diaphragm to the "bony apex of the thoracic line" and to the fascia stretched across the thoracic apex, and they may be called the "superior tendinous crura." It is thus evident that the deep cervical fascia is connected to the lateral and superior parts of the pericardium. At birth the muscular

ported by many observations made on the human subject under various conditions of disease, and on living animals after the muscles have been exposed under chloroform. The reader may consult an interesting paper by Dr. Cleland in the Journal of Anat. and Phys., No. II., May, 1867, p. 209. On the Hutchinsonian Theory of the Action of the Intercostal Muscles, who refers also to Henle, Luschka, Budge, and Baumler. Observations on the Action of the Intercostal Muscles, Erlangen, 1860. (In New Syd. Soc.'s Year-book for 1861, p. 68.) Dr. W. W. Keen has come to the conclusion, from experiments made upon a criminal executed by hanging, that the External intercostals are muscles of expiration, as they pulled the ribs down, while the Internal intercostals pulled the ribs up and are muscles of inspiration (Trans. Coll. Phys., Philadelphia, Third Series, vol. I., 1875, p. 97).

¹ For a detailed description of the general relations of the Diaphragm, and its action, refer to Dr. Sibson's Medical Anatomy.
² American Journal of the Medical Sciences, July, 1880.
fibres of the Diaphragm contract at the first inspiration. The ductus arteriosus is lodged in an elliptical opening of a tendinous scaffolding. The contractions of the Diaphragm cause the tendinous scaffolding to compress the ductus arteriosus "and eventually close it." The chief agents in the compression are the muscular fibres which pass from the Diaphragm to the pericardium. When the lateral wings of the Diaphragm descend they tend to form a vacuum in the thorax and thus assist the venous circulation.

"The descent of the Diaphragm is not necessary to respiration," but it "is necessary in order to protect the heart from the movement of surrounding viscera, and in order to promote the free circulation of the blood through the vessels forming the cardiac roots."

Muscles of Inspiration and Expiration.—The muscles which assist the action of the Diaphragm in ordinary tranquil inspiration are the Intercostals and the Levatores costarum, as above stated, and the Scaleni. When the need for more forcible action exists, the shoulders and the base of the scapula are fixed, and then the powerful muscles of forced inspiration come into play; the chief of these are the Trapezius, the Pectoralis minor, the Serratus posticus superior and inferior, and the Rhomboidei. The lower fibres of the Serratus magnus may possibly assist slightly in dilating the chest by raising and evertting the ribs. The Sterno-mastoid also, when the head is fixed, assists in forced inspiration by drawing up the sternum and by fixing the clavicle, and thus affording a fixed point for the action of the muscles of the chest. The Ilio-costalis and Quadratus lumborum assist in forced inspiration by fixing the last rib.

The ordinary action of expiration is hardly effected by muscular force, but results from a return of the walls of the thorax to a condition of rest, owing to their own elasticity and to that of the lungs. Forced expiratory actions are performed mainly by the flat muscles (Obliqui and Transversalis) of the abdomen, assisted by the Rectus. Other muscles of forced expiration are the Internal intercostals and Triangularis sterni (as above mentioned).†

III. MUSCLES OF THE ABDOMEN.

The muscles of the abdomen may be divided into two groups: 1. The superficial muscles of the abdomen. 2. The deep muscles of the abdomen.

1. The Superficial Muscles of the Abdomen.

The Muscles in this region are, the

External Oblique. Transversalis.
Internal Oblique. Rectus.
Pyramidalis.

Dissection (Fig. 288).—To dissect the abdominal muscles, make a vertical incision from the ensiform cartilage to the symphysis pubis; a second incision from the umbilicus obliquely upward and outward to the outer surface of the chest, as high as the lower border of the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outward to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outward, in the lines of direction of the muscular fibres. If necessary, the abdominal muscles may be made tense by inflating the peritoneal cavity through the umbilicus.

† A. M. Patterson (article on Myology, in D. J. Cunningham’s Text-book of Anatomy) states that the movement of inspiration is performed by the elasticity of the lungs, the weight of the chest-wall, the elevation of the Diaphragm, the action of the Triangularis sterni and muscles of the abdominal wall, possibly aided by the interosseous fibres of the Internal intercostal muscles. The same author states that the movement of inspiration is performed ordinarily by the descent of the Diaphragm and the action of this muscle in elevating the ribs, the action of the External intercostals and Levatores costarum, probably the action of the whole of each Internal intercostal, of the Scaleni, and of the Serrati postici. The necessary muscles of respiration are employed when voluntary respiratory effort is necessary. Patterson names them as follows: The Quadratus lumborum, Pectorales, Serratus magnus, Sterno-mastoid, Latissimus dorsi, Infra-hyoid muscles, Extensors of the spine.
Superficial Fascia.—The superficial fascia of the abdomen consists, over the greater part of the abdominal wall, of a single layer of fascia, which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands. The superficial layer of the superficial fascia, or the fascia of Camper, is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below it passes over Poupart’s ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale hue, it has a reddish color, and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward to be continuous with the superficial fascia of the perineum. In the female this fascia is continued into the labia majora. The deep layer of the superficial fascia or the fascia of Scarpa, is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba and to the synphysis pubis, and is prolonged on to the dorsum of the penis, forming the suspensory ligament of the penis; above, it joins the superficial layer and is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart’s ligament; and below and internally it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the deep layer of the superficial fascia of the perineum. In the female it is continued into the labia majora.

Deep Fascia.—The deep fascia invests the external oblique muscle, but is so thin over the aponeurosis of the muscle as to be scarcely recognizable.

The External or Descending Oblique Muscle (m. obliquus externus abdominis) (Fig. 289) is situated on the side and forepart of the abdomen; being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall, of the abdomen. It arises, by eight fleshy digitations, from the external surface and lower borders of the eight inferior ribs; these digitations are arranged in an oblique line running downward and backward; the upper ones being attached close to the cartilages of the corresponding ribs; the lowest, to the apex of the cartilage of the last rib; the intermediate ones, to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downward, and are received between corresponding processes of the Serratus magnus; the three lower ones diminish in size from above downward, receiving between them corresponding processes from the Latisimus dorsi. From these attachments, the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downward, to be inserted into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downward and forward, terminate in an aponeurosis, oppo-
site a line drawn from the prominence of the ninth costal cartilage to the anterior superior spinous process of the ilium.

**Aponeurosis of External Oblique.**—The aponeurosis of the external oblique is a thin, but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. It is joined with that of the opposite muscle along the median line, covers the whole of the front of the abdomen; above, it is connected with the lower border of the Pectoralis major; below, its fibres are closely

aggregated together, and extend obliquely across from the anterior superior spine of the ilium to the spine of the os pubis and the linea ilio-pectinea. In the *median line* it interlaces with the aponeurosis of the opposite muscle, forming the *linea alba*, which extends from the ensiform cartilage to the symphysis pubis.

That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward, and continuous below with the fascia lata; it is called *Poupart's ligament* or the
ligament of Fallopius. The portion which is reflected from Poupart’s ligament at the spine of the os pubis along the pectineal line is called Gimbernat’s ligament. From the point of attachment of the latter to the pectineal line, a few fibres pass upward and inward, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin, triangular, fibrous layer, which is called the triangular fascia of the abdomen or Colles’s ligament (ligamentum inguinale reflexum). The point of the triangle is at the origin of Colles’s ligament; the base is at the linea alba. Colles’s ligament is in front of the conjoined tendon, the Rectus muscle, and the Pyramidalis muscle.

In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the external abdominal ring, formed by a separation of the fibres of the aponeurosis in this situation.

![Diagram of the male external abdominal ring and saphenous opening](image)

**Fig. 290.—Right external abdominal ring and saphenous opening in the male.** (Spalteholz.)

**Relations.**—By its external surface, with the superficial fascia, superficial epigastric and circumflex iliac vessels, and some cutaneous nerves; by its internal surface, with the Internal oblique, the lower part of the eight inferior ribs, and Intercostal muscles, the Cremaster, the spermatic cord in the male, and round ligament in the female. Its posterior border, extending from the last rib to the crest of the ilium, is fleshy throughout and free; it is occasionally overlapped by the Latissimus dorsi, though generally a triangular interval exists between the two muscles near the crest of the ilium, in which is seen a portion of the internal oblique. This triangle, Petit’s triangle (trigonum lumbale), is therefore bounded in front by the External oblique, behind by the Latissimus dorsi, below by the crest of the ilium, while its floor is formed by the Internal oblique (Fig. 289).

The following parts of the aponeurosis of the External oblique muscle require to be further described—viz., the external abdominal ring, the intercoolumnar fibres and fascia, Poupart’s ligament, Gimbernat’s ligament, and the triangular fascia of the abdomen.
The External Abdominal Ring (annulus inguinalis subcutaneus) (Fig. 290).—
Just above and to the outer side of the crest of the os pubis an interval is seen in the
aponeurosis of the External oblique, called the external abdominal ring. The aperture
is oblique in direction, somewhat triangular in form, and corresponds with the
course of the fibres of the aponeurosis. It usually measures from base to apex
about an inch, and transversely about half an inch. It is bounded below by the
crest of the os pubis; above, by a series of curved fibres, the external spermatic, or the
intercolumnar fibres (fibrae intercrurales), which pass across the upper angle of
the ring, so as to increase its strength; and on each side, by the margins of the
opening in the aponeurosis, which are called the columns or pillars of the ring.
The External Pillar or inferior crus (crus inferius) is inferior from the obliquity
of its direction. It is stronger than the internal pillar; it is formed by that
portion of Poupart’s ligament which is inserted into the spine of the os pubis; it is
curved so as to form a kind of groove, upon which the spermatic cord rests.
The Internal Pillar or superior crus (crus superius) is a broad, thin, flat band,
which is attached to the front of the symphysis pubis, interlacing with its fellow
of the opposite side.

The external abdominal ring gives passage to the spermatic cord in the male
(funiculus spermaticus) and round ligament in the female (ligamentum teres uteri): it is much larger in men than in women, on account of the large size of the sper-
matic cord, and hence the greater frequency of inguinal hernia in men.

Intercolumnar Fibres (fibrae intercrurales) (Fig. 290).—The intercolumnar fibres
are a series of curved tendinous fibres, which arch across the lower part of the
aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring, describing a curve
with the convexity downward. They are much thinner and stronger at the outer
margin of the external ring, where they are connected to the outer third of Pou-
part’s ligament, than internally, where they are inserted into the linea alba. They
are more strongly developed in the male than in the female. The inter-
columnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another.

These intercolumnar fibres as they pass across the external abdominal ring
are themselves connected together by delicate fibrous tissue, thus forming a fascia,
which as it is attached to the pillars of the ring covers it in, and is called the
intercolumnar fascia or the external spermatic fascia. This intercolumnar fascia
is continued down as a tubular prolongation around the outer surface of the
cord and testis or of the round ligament, and encloses them in a distinct sheath.

The sac of an inguinal hernia, in passing through the external abdominal ring, receives an
investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external abdominal ring
and the limb is then extended and rotated outward, the aponeurosis of the External
oblique, together with the iliac portion of the fascia lata, will be felt to become
tense, and the external ring much contracted; if the limb is, on the contrary, flexed
upon the pelvis and rotated inward, this aponeurosis will become lax and the external abdominal ring sufficiently enlarged to admit the finger with compara-
tive ease; hence the patient should always be put in the latter position when the
taxis is applied for the reduction of an inguinal hernia in order that the abdominal
walls may be relaxed as much as possible.

Poupart’s Ligament (ligamentum inguinale).—The portion of Poupart’s ligament
in front of the crural ring is called the superficial crural arch. Poupart’s ligament
is the lower border of the aponeurosis of the External oblique muscle, and extends
from the anterior superior spine of the ilium to the pubic spine. From this
latter point it is reflected outward to be attached to the pectineal line for about
half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between the crural arch and the innominate bone is filled in by the parts which descend from the abdomen into the thigh (Fig. 298). These will be referred to again on a subsequent page.

Gimbernat's Ligament (ligamentum lacunare) (Figs. 290 and 298).—Gimbernat's ligament is that part of the aponeurosis of the External oblique muscle which is reflected upward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base directed outward. Its base, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath, forming the inner boundary of the femoral or crural ring (annulus femoralis). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament. Its surfaces are directed upward and downward.

Triangular Fascia or Colles's Ligament (ligamentum inguinale reflexum).—The triangular fascia of the abdomen is a layer of tendinous fibres of a triangular shape, which is attached by its apex to the pectineal line, where it is continuous with Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring, and in front of the conjointed tendon, and interlaces with the ligament of the other side at the linea alba.

Ligament of Cooper (Fig. 298).—This is a strong ligamentous band, which was first described by Sir Astley Cooper. It extends upward and backward from the base of Gimbernat's ligament along the ilio-pectineal line, to which it is attached. It is strengthened by the fascia transversalis, by the pectineal aponeurosis, and by a lateral expansion from the lower attachment of the linea alba (adminiculum lineae albae).

Suspensory Ligament of the Penis (ligamentum fundiforme penis).—The suspensory ligament of the penis arises from the linea alba, the anterior portion of the sheath of the Rectus muscle, and the superficial fascia. It splits into two portions, blends with the inserting fascia of the penis, and passes into the scrotum.

Suspensory Ligament of the Clitoris (ligamentum fundiforme clitoridis).—The suspensory ligament of the clitoris corresponds in the female to the suspensory ligament of the penis in the male.

Dissection.—Detach the External oblique by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then separate the muscle carefully from the Internal oblique, which lies beneath, and turn it toward the opposite side.

The Internal or Ascending Oblique Muscle (m. obliquus internus abdominis) (Fig. 291), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form, and is situated at the side and forepart of the abdomen. It arises, by fleshy fibres, from the outer half of Poupart's ligament, being attached to the groove on its upper surface; from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia (Fig. 295). From this origin the fibres diverge: those from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord in the male and the round ligament in the female, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, to the extent of half an inch or more, forming what is known as the conjointed tendon of the Internal oblique and
Transversalis; those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be inserted into the linea alba; those which arise from the middle third of the origin from the crest of the ilium pass obliquely upward and inward, and terminate in an aponeurosis which divides at the outer border of the Rectus muscle into two lamellae (Fig. 296), which are continued forward, in front and behind this muscle, to the linea alba, the posterior lamella being also connected to the cartilages of the seventh, eighth, and ninth ribs; the most posterior fibres pass almost vertically upward, to be inserted into the lower borders of the cartilages of the three lower ribs, being continuous with the Internal intercostal muscles.

The conjoined tendon of the **Internal oblique** and **Transversalis** is *inserted* into the crest of the os pubis and pectineal line, immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of a protrusion through the external ring, forming one of the coverings of direct inguinal hernia; or the hernia forces its way through the fibres of the conjoined tendon. The conjoined tendon is sometimes divided into an outer and an inner portion—the former being termed the ligament of Hesselbach (*ligamentum interfoveolare*); the latter, the ligament of Henle (Fig. 292).
Aponeurosis of Internal Oblique.—The aponeurosis of the Internal oblique is continued forward to the middle line of the abdomen, where it joins with the aponeurosis of the opposite muscle at the linea alba, and extends from the margin of the thorax to the os pubis. At the outer margin of the Rectus muscle this aponeurosis, for the upper three-fourths of its extent, divides into two lamellae, which pass, one in front and the other behind the muscle, enclosing it in a kind of sheath, and reuniting on its inner border of the linea alba; the anterior layer is blended with the aponeurosis of the External oblique muscle; the posterior layer with that of the Transversalis. Along the lower fourth the aponeurosis passes altogether in front of the Rectus without any separation. Where the aponeurosis ceases to split, and passes altogether in front of the Rectus muscle, a deficiency is left in the sheath of the muscle behind; this is marked above by a sharp lunated margin having its concavity downward. This is known as the semilunar fold of Douglas (linea semicircularis) (Fig. 293).

Relations.—By its external surface, with the External oblique, Latissimus dorsi, spermatic cord, and external ring; by its internal surface, with the Transversalis muscle, the lower intercostal vessels and nerves, the ilio-hypogastric and the ilioinguinal nerves. Near Poupart’s ligament it lies on the fascia transversalis, internal ring, and spermatic cord. Its lower border forms the upper boundary of the inguinal canal.

The Cremaster muscle (Fig. 291) is a thin, muscular layer, composed of a number of fasciculi which arise from the inner part of Poupart’s ligament, where its fibres are continuous with those of the Internal oblique and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the middle
spermatic fascia (fascia cremasterica). The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

Fig. 293.—The muscles of the abdomen, showing the semilunar fold of Douglas. Viewed from in front. (Spalteholz.)

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched fibres of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum. It occasionally happens
that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis, in its descent, passed through instead of beneath the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal hernia. The Cremaster muscle is found only in the male, but almost constantly in the female

Fig. 294.—The Transversalis, Rectus, and Pyramidalis muscles.

a few muscular fibres may be seen on the surface of the round ligament, which correspond to this muscle, and in cases of oblique inguinal hernia in the female a considerable amount of muscular fibre may be found covering the sac.

Dissection.—Detach the Internal oblique in order to expose the Transversalis beneath. This may be effected by dividing the muscle, above, at its attachment to the ribs; below, at its connection with Poupart's ligament and the crest of the ilium; and behind, by a vertical incision
extending from the last rib to the crest of the ilium. The muscle should previously be made
tense by drawing upon it with the fingers of the left hand, and if its division is carefully effected,
the cellular interval between it and the Transversalis, as well as the direction of the fibres of the
latter muscle, will afford a clear guide to their separation; along the crest of the ilium the circumflex iliac vessels are interposed between them, and form an important guide in separating
them. The muscle should then be thrown inward toward the linea alba.

The Transversalis Muscle (*m. transversus abdominis*) (Fig. 294), so called
from the direction of its fibres, is the most internal flat muscle of the abdomen, being placed immediately beneath the Internal oblique. It *arises* by fleshly fibres
from the outer third of Poupart's ligament; from the inner lip of the crest of the
ilium for its anterior three-fourths; from the inner surface of the cartilages of the
six lower ribs, interdigitating with the Diaphragm; and from the lumbar fascia
(Fig. 295), which may be regarded as the posterior aponeurosis of the muscle. The muscle terminates in front in a broad aponeurosis, the lower fibres of
which curve downward and inward, and are *inserted*, together with those of the
Internal oblique, into the lower part of the linea alba, the crest of the os pubis
and pectineal line forming what is known as the conjoined tendon of the Internal
oblique and Transversalis. The lowermost fibres help to form the posterior wall
of the inguinal canal. Throughout the rest of its extent the aponeurosis passes
horizontally inward, and is *inserted* into the linea alba, its upper three-fourths
passing behind the Rectus muscle, blending with the posterior lamella of the
Internal oblique; its lower fourth passing in front of the Rectus. The external
portion of the lower fibres of the conjoined tendon is known as the ligament
of Hesselbach; the internal portion as the ligament of Henle.

Relations.—By its external surface, with the Internal oblique, the lower inter-
costal nerves, and the inner surface of the cartilages of the lower ribs; by its
internal surface, with the fascia transversalis, which separates it from the periton-
eum. Its lower border forms the upper boundary of the inguinal canal.

Dissection.—To expose the Rectus muscle, open its sheath by a vertical incision extending
from the margin of the thorax to the os pubis, and then reflect the two portions from the surface
of the muscle, which is easily done, excepting at the linea transverse, where so close an adhesion
exists that the greatest care is requisite in separating them. Now raise the outer edge of the
muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the
centre, and turning its lower part downward, the point where the posterior wall of the sheath
terminates in a thin curved margin will be seen.

The Rectus Abdominis (Figs. 292, 294 and 296) is a long flat muscle, which
extends along the whole length of the front of the abdomen, being separated from
its fellow of the opposite side by the linea alba. It is much broader, but thinner,
above than below, and *arises* by two tendons, the external or larger being attached
to the crest of the os pubis, the internal, smaller portion interlacing with its fellow of
the opposite side, and being connected with the ligaments covering the front of the
symphysis pubis. The fibres ascend, and the muscle is inserted by three portions of
unequal size into the cartilages of the fifth, sixth, and seventh ribs. The upper portion,
attached principally to the cartilage of the fifth rib, usually has some fibres of
insertion into the anterior extremity of the rib itself. Some fibres are occasionally
connected with the costo-xiphoid ligaments and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number,
which have received the name of **lineae transverseae**. One of these is usually
situated opposite the umbilicus, and two above that point; of the latter, one
corresponds to the extremity of the ensiform cartilage, and the other to the inter-
val between the ensiform cartilage and the umbilicus. These intersections pass
transversely or obliquely across the muscle in a zigzag course; they rarely extend
completely through its substance, sometimes they pass only half-way across it, and
are intimately adherent in front to the sheath in which the muscle is enclosed.
Sometimes one or two additional lines may be seen, one usually below the umbilicus; the position of the other, when it exists, is variable. These additional lines are for the most part incomplete.

Fig. 295.—A transverse section of the abdomen in the lumbar region.

The Rectus is enclosed in a sheath, the rectus sheath (vagina m. recti abdominis) (Figs. 295 and 296), formed by the aponeurosis of the Oblique and Transversalis muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus it divides into two lamellæ,
one of which passes in front of the Rectus, blending with the aponeurosis of the External oblique; the other, behind it, blending with the aponeurosis of the Transversalis; and these, joining again at its inner border, are inserted into the linea alba. This arrangement of the aponeuroses exists along the upper three-fourths of the muscle: at the commencement of the lower fourth, the posterior wall of the sheath terminates in a thin curved margin, the semilunar fold of Douglas (linea semicircularis) (Fig. 293), the concavity of which looks downward toward the pubes; the aponeuroses of all three muscles passing in front of the Rectus without any separation. A very thin aponeurotic layer does pass behind the lower one-fourth of the muscle, but it is trivial as compared with the thickness of the layer behind the upper three-fourths of the muscle. This sudden thinning causes the semilunar fold of Douglas. The extremities of the fold of Douglas descend as pillars to the os pubis. The inner pillar is attached to the symphysis pubis; the outer pillar passes downward as a distinct band on the inner side of the internal abdominal ring to join with the outer fibres of the conjoined tendon, and assist to form the ligament of Hesselbach. There its fibres divide into two sets, internal and external; the internal fibres are attached to the ascending ramus of the os pubis and the pectineal fascia; the external ones pass to the Psoas fascia, to the deep surface of Poupart's ligament, and to the tendon of the Transversalis on the outer side of the ring. The Rectus muscle, in the situation where its sheath is deficient, is separated from the peritoneum by the transversalis fascia. The convex outer border of the Rectus muscle corresponds to the linea semilunaris.

The Pyramidalis is a small muscle, triangular in shape, placed at the lower part of the abdomen, in front of the Rectus, and contained in the same sheath with that muscle. It arises by tendinous fibres from the front of the os pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upward, diminishing in size as it ascends, and terminates by a pointed extremity, which is inserted into the linea alba, midway between the umbilicus and the os pubis. This muscle is sometimes found wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it has been found double on one side, or the muscles of the two sides are of unequal size. Sometimes its length exceeds what is stated above.

Besides the Rectus and Pyramidalis muscles, the sheath of the Rectus contains the superior and deep epigastric arteries, the terminations of the lumbar arteries and of the lower intercostal arteries and nerves.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Transversalis and Internal oblique also receive filaments from the hypogastic branch of the ilio-hypogastric and sometimes from the ilio-inguinal. The Cremaster is supplied by the genital branch of the Genito-crural.

In the description of the abdominal muscles mention has frequently been made of the linea alba, linea semilunares, and linea transversæ; when the dissection of the muscles is completed these structures should be examined.

The Linea Alba (Figs. 293 and 296).—The linea alba is a tendinous raphé seen along the middle line of the abdomen, extending from the ensiform cartilage to the symphysis pubis, to which it is attached. It is placed between the inner borders of the Recti muscles, and is formed by the blending of the aponeuroses of the Obliqui and Transversales muscles. It is narrow below, corresponding to the narrow interval existing between the Recti; but broader above, as these muscles diverge from one another in their ascent, becoming of considerable breadth when there is great distention of the abdomen from pregnancy or ascites. It presents numerous apertures for the passage of vessels and nerves: the largest of these is the umbilicus (Fig. 297). The umbilicus is a fibrous ring formed by the fibres of the aponeurosis of the linea alba, is filled with scar tissue; in the fetus transmits the umbilical vein, the two hypogastric arteries, the allantoic duct, and the vitello-intestinal duct; but in the
adult is obliterated, the cicatrix being stronger than the neighboring parts; hence umbilical hernia occurs in the adult near the umbilicus, whilst in the foetus it occurs at the umbilicus. The remains of the foetal structures are cord-like in character, and they diverge from the umbilicus within the abdomen. The remains of the umbilical vein constitute the round ligament of the liver, and this cord passes upward (Fig. 297). The remains of the hypogastric arteries pass downward (Fig. 297). The remains of the allantois become the urachus, which passes to the summit of the bladder (Fig. 297). The depression of the umbilicus was created by the urachus. The linea alba is in relation, in front, with the integument, to which it is adherent, especially at the umbilicus; behind, it is separated from the peritoneum by the transversalis fascia; and below, by the urachus, and the bladder when that organ is distended.

The Lineae Semilunares (Fig. 289).—The lineae semilunares are two curved tendinous lines placed one on each side of the linea alba. Each corresponds with the outer border of the Rectus muscle, extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, where it is reinforced in front by the External oblique and behind by the Transversalis. The Lineae Transverseae (inscriptiones tendineae) (Fig. 289).—The lineae transverseae are narrow transverse lines which intersect the Recti muscles, as already mentioned; they connect the lineae semilunares with the linea alba.

Actions.—The abdominal muscles perform a threefold action:

When the pelvis and thorax are fixed, they compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the Diaphragm. By these means the foetus is expelled from the uterus, the feces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and spine are fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone is fixed, the thorax is bent directly forward when the muscles of both sides act, or to either side when those of the two sides act alternately, rotation of the trunk at the same time taking place to the opposite side.

If the thorax is fixed, these muscles, acting together, draw the pelvis upward, as in climbing; or, acting singly, they draw the pelvis upward, and bend the vertebral column to one side or the other. The Recti muscles, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidalis are tensors of the linea alba.

The Transversalis Fascia (fascia transversalis).—The fascia transversalis is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the extra-peritoneal fat. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciae. In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle, but it becomes thin and cellular as it ascends to the Diaphragm, and blends with the fascia covering this muscle. In front, it unites across the middle line with the fascia on the opposite side of the body, and behind it becomes
lost in the fat which covers the posterior surfaces of the kidneys. Below, it has the following attachments: posteriorly, it is connected to the whole length of the crest of the ilium, between the attachments of the Transversalis and Iliacus muscles; between the anterior superior spine of the ilium and the femoral vessels it is connected to the posterior margin of Poupart’s ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the os pubis and pectineal line, behind the conjointed tendon, with which it is united; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the crural sheath. Beneath Poupart’s ligament it is strengthened by a band of fibrous tissue, which is only loosely connected to Poupart’s ligament, and is specialized as the deep crural arch. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the internal abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on these structures, forming the infundibuliform fascia.

The internal or deep abdominal ring (annulus inguinalis abdominis) (Figs. 292 and 298) is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart’s ligament. It is of an oval form, the extremities of the oval directed upward and downward, varies in size in different subjects, and is much larger in the male than in the female. Its lower border is strengthened by the collection of fibres called Hesselbach’s ligament, lying directly in front of the deep epigastric artery. It is the outer portion of the conjointed tendon fused with the outer pillar of the semilunar fold of Douglas. The internal ring is bounded, above and externally, by the arched fibres of the Transversalis; below and internally, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the infundibuliform or internal spermatic fascia, is continued round the cord and testis, enclosing them in a distinct pouch.
OF THE ABDOMEN

Fig. 299.—The right inguinal canal in the male, second layer, viewed from in front. (The first layer is shown in Fig. 290.) (Spalteholz.)

Fig. 300.—The right inguinal canal in the male, third layer, viewed from in front. (Spalteholz.)
When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The Inguinal or Spermatic Canal (canalis inguinalis) (Figs. 299 and 300).—The inguinal or spermatic canal contains the spermatic cord (funiculus spermaticus) in the male and the round ligament (ligamentum teres uteri) in the female. It is an oblique canal about an inch and a half in length, directed downward and inward, and placed parallel to and a little above Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded in front by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; behind, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; above, by the arched fibres of the Internal oblique and Transversalis; below, by Gimbernat's ligament, and by the union of the fascia transversalis with Poupart's ligament. The median aspect of the floor of the canal is strengthened by dense fibres which are attached to the pubis and to the Rectus muscle. These fibres constitute the falc inguinalis. The deep epigastric artery passes upward and inward behind the canal lying close to the inner side of the internal abdominal ring (Fig. 292). The interval between this artery and the outer edge of the Rectus is named Hesselbach's triangle, the base of which is formed by Poupart's ligament.

That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called oblique inguinal hernia.

The Deep Crural Arch.—Curving over the vessels, just at the point where they become femoral, on the abdominal side of Poupart's ligament and loosely connected with it, is a thickened band of fibres called the deep crural arch. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath to be inserted by a broad attachment into the spinous of the os pubis and ilio-pectineal line, behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting.

Cooper's Ligament or the Reflected Tendon of Cooper (Fig. 298) is a small reflection from the tendon of the Transversalis which passes downward and outward behind Gimbernat's ligament.

Surface Form.—The only two muscles of this group which have any considerable influence on surface form are the External oblique and Rectus muscles of the abdomen. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked, intermingled with the serrations of the Serratus magnus; the lower digitations are not visible, being covered by the thick border of the Latissimus dorsi. Its attachment to the crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the ilioc furrrow. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscular fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the linea semilunaris, which may be exactly defined by putting the muscle into action. It corresponds with a curved line, with its convexity outward, drawn from the end of the cartilage of the ninth rib to the spine of the os pubis, so that the centre of the line, at or near the umbilicus, is three inches from the median line. The inner border of the Rectus corresponds to the linea alba, marked on the surface of the body by a groove, the abdominal furrow, which extends from the infrasternal fossa to, or to a little below, the umbilicus, where it gradually becomes lost. The surface of the Rectus presents three transverse furrows, the linea transversae. The upper two of these, one opposite or a little below the tip of the ensiform cartilage, and another, midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the linea alba, varies very much in position as regards its level. It is always situated above a zone drawn round the body opposite the highest point of the crest of the ilium, generally being about three-quarters of an inch to an inch above this line. It usually corresponds, therefore, to the fibro-cartilage between the third and fourth lumbar vertebrae.
2. The Deep Muscles of the Abdomen.

Psoas magnus. Iliacus.
Psoas parvus. Quadratus lumborum.

The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fascia covering them, will be described with the Muscles of the Lower Extremity.

The Fascia Covering the Quadratus Lumborum (Fig. 295).—This is the most anterior of the three layers of the lumbar fascia. It is a thin layer of fascia, which, passing over the anterior surface of the Quadratus lumborum, is attached, internally, to the bases of the transverse processes of the lumbar vertebrae; below, to the ilio-lumbar ligament; and above, to the apex and lower border of the last rib.

The portion of this fascia which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib constitutes the ligamentum arcuatum externum.

The Quadratus Lumborum (Fig. 283) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the ilio-lumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is inserted into the lower border of the last rib for about half its length, and by four small tendons, into the apices of the transverse processes of the four upper lumbar vertebrae. Occasionally a second portion of this muscle is found situated in front of the preceding. This arises from the upper borders of the transverse processes of three or four of the lower lumbar vertebrae, and is inserted into the lower margin of the last rib. The Quadratus lumborum is contained in a sheath formed by the anterior and middle lamellae of the lumbar fasciae.

Relations.—Its anterior surface (or rather the fascia which covers its anterior surface) is in relation with the colon, the kidney, the Psoas muscle, and the Diaphragm. Between the fascia and the muscle are the last dorsal, ilio-hypogastric, and ilio-inguinal nerves. Its posterior surface is in relation with the middle lamella of the lumbar fascia, which separates it from the Erector spine. The Quadratus lumborum extends, however, beyond the outer border of the Erector spine.

Nerve-supply.—The anterior branches of the last dorsal and first lumbar nerves; sometimes also a branch from the second lumbar nerve.

Actions.—The Quadratus lumborum draws down the last rib. It acts as a muscle of inspiration by helping to fix the origin of the Diaphragm. If the thorax and spine are fixed, it may act upon the pelvis, raising it toward its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

IV. MUSCLES OF THE PELVIC OUTLET.

The muscles of this region are situated at the pelvic outlet in the ischio-rectal region and the perineum. They include the following:

1. Muscles of the ischio-rectal region.
2. Muscles of the perineum in the male.
3. Muscles of the perineum in the female.

1. The Muscles of the Ischio-rectal Region.

Corrugator cutis ani. Internal sphincter ani.
External sphincter ani. Levator ani.

Coccygeus.

The Corrugator Cutis Ani.—Around the anus is a thin stratum of involuntary muscular fibre, which radiates from the orifice. Internally, the fibres fade off
into the submucous tissue, while externally they blend with the true skin. By its contraction it raises the skin into ridges around the margin of the anus.

The External Sphincter Ani (m. sphincter ani externus) (Figs. 301, 306, 307, and 308) is a thin, flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length from its anterior to its posterior extremity, being about an inch in breadth opposite the anus. It arises from the tip and back of the coccyx by a narrow tendinous band, and from the superficial fascia in front
OF THE ISCHIO-RECTAL REGION

of that bone; and is inserted into the raphé of the Accelerator urine muscle and into the central tendinous point of the perineum, joining with the two Superficial transverse perineal, the Levator ani, and the Accelerator urine muscles. Many of the fibres are continuous with the Accelerator urine in the male and with the Sphincter vaginae in the female. Often some of the fibres are continuous with the Transverse perineal muscles. It is continuous above with the Levator ani. Like other sphincter muscles, it consists of two planes of muscular fibre, which surround the margin of the anus and join in a commissure in front and behind, some fibres crossing from side to side in front and behind the anus.

Nerve-supply.—A branch from the anterior division of the fourth sacral and the inferior hemorrhoidal branch of the internal pudic.

Actions.—The action of this muscle is peculiar: 1. It is, like other sphincter muscles, always in a state of tonic contraction, and having no antagonistic muscle, it keeps the anal orifice closed. 2. It can be put into a condition of greater con-

traction under the influence of the will, so as to occlude more firmly the anal aperture in expiratory efforts unconnected with defecation. 3. Taking its fixed point at the coccyx, it helps to fix the central point of the perineum, so that the Accelerator urinae may act from this fixed point.

The Internal Sphincter Ani (m. sphincter ani internus) is a muscular ring which surrounds the lower extremity of the rectum for about an inch, its inferior border being contiguous to, but quite separate from, the External sphincter. This muscle is about two lines in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. It is paler in color and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

The Levator Ani (Figs. 302, 303, 304, and 305) is a broad, thin muscle, situated on each side of the pelvis. It is attached to the inner surface of the
sides of the true pelvis, and, descending, unites with its fellow of the opposite side to form the floor of the pelvic cavity. It supports the viscerae in this cavity and surrounds the various structures which pass through it. It is usually possible to detect an interval between the fibres rising from the pubis and those rising from the pelvic fascia, and this interval marks the fact that the muscle described as one is really two. The pubic fibres constitute the Pubococcygeus muscle and the other fibres the Iliococcygeus muscle.\(^1\)

The Pubococcygeus muscle takes origin from the posterior aspect of the ramus of the pubis and from the most anterior portion of the tendinous arch of the Levator ani muscle. The fibres of origin from the pubis surround anteriorly the origin of the Internal obturator muscle. The muscle is a band, about one inch in width, thickest at its outer border, where it overlaps the Iliococcygeus. It passes backward, downward, and inward, “near the prostate in the male, the urethra and vagina in the female,”\(^2\) and near to the rectum. Most of the fibres pass back of the rectum, where they meet and join with the corresponding fibres of the opposite side. These united fibres form a thick, tendinous aponeurosis. “This is continued upward in front of the coccyx for some distance, and finally divides into two lateral portions, which have been named the ligamenta sacro-coccygea anterior. They are situated on either side of the middle sacral artery, and are finally inserted into the last one or two pieces of the sacrum and the first piece of the coccyx.”\(^3\) A few of the fibres of the Pubococcygeus muscle pass to the

---

1 Peter Thompson. *The Myology of the Pelvic Floor.*
2 Spalteholz’s Atlas. Translated and edited by Barker.
3 Peter Thompson. *The Myology of the Pelvic Floor.*
central tendon of the perineum, come in contact with but do not terminate in the rectal wall, descend in front of and close to the anterior rectal wall, and terminate in the anterior portion of the sphincter ani and in the skin of the anus (Peter Thompson).

Luschka and others believe that these anterior fibres descend among the longitudinal fibres of the rectum. It is certain that the most anterior fibres of the

Pubococcygeus muscle pass to the central point of the perineum. They pass "backward and downward on the side of the prostate, and in some cases on the side of the urethra immediately it emerges from the prostate." These anterior fibres in the female descend upon the side of the vagina. The anterior fibres are the preanal fibres of the Levator ani. They constitute what Santorini named

1 Peter Thompson. The Myology of the Pelvic Floor.
the levator prostateae, because he regarded them as constituting a distinct muscle, which surrounds the prostate as a sling. Krause calls these fibres the levator urethreæ; Testut, the fibres pré-rectales, and Prout, the Recto-urethralis muscle.

The iliococcygeus muscle arises from the tendinous arch of the Levator ani muscle (arcus tendineus m. levatoris ani). This arch is concave upward. The anterior end of the arch begins on the posterior surface of the superior ramus of the pubis. "The posterior end can be followed as far as the linea arcuata of the ilium, between these two points it descends for a variable distance, but always leaves the canalis obturatorius free." The fibres, coursing internally and downward, pass below the posterior portion of the Pubococcygeus. The anterior fibres join the fibres of the other side, between the anus and the tip of the coccyx in a median raphé.

The posterior fibres are inserted into the sides of the last two pieces and into the tip of the coccyx. Peter Thompson points out that the iliococcygeus muscle is liable to variations. It is strongly developed in but few, is usually thin, the muscular bundles being separated by membranous intervals; it may be replaced by fibrous tissue and may even be absent.

Relations of the Levator Ani.—By its inner or pelvic surface, with the rectovesical fascia, which separates it from the viscera of the pelvis and from the peritoneum. By its outer or perineal surface, it forms the inner boundary of the ischio-rectal fossa, and is covered by a thin layer of fascia, the ischio-rectal or anal fascia, given off from the obturator fascia. Its posterior border is free and separated from the Coccygeus muscle by a cellular interspace. Its anterior border is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, passes from the pelvis.

Nerve-supply.—A branch from the anterior division of the fourth sacral nerve and a branch from the pudic nerve, which is sometimes derived from the perineal and sometimes from the inferior hemorrhoidal division.

Actions.—The entire Levator ani muscle enters into the formation of the diaphragm of the pelvis and aids in supporting the rectum, vagina, and bladder.

---

2 Myology of Muscles.
The two parts of the muscle have different functions. The Iliococcygei have no other function than that of supporting the viscera. In early life they flex the vertebrae of the coccyx on one another and flex the coccyx on the sacrum, but do not act directly at any age on the rectum or pelvic viscera (Peter Thompson). The Pubococcygei, especially in the female, have most important functions. They are the most influential supports of the pelvic floor and restore the pelvic floor to its proper position after the depression induced by parturition, defecation, and efforts at urination.^1 Normally, they pull the perineum upward after the descending head has pulled it down. In some cases the contraction of the muscles actually obstructs the descent of the head (Peter Thompson). The muscles are strongly developed in females, and, acting with the Sphincter vaginae, they aid in contracting the vaginal canal. The muscles constrict the rectum and also lift the rectum with the pelvic floor. During defecation the position of the rectal contents is maintained by intra-abdominal pressure, the muscles lift the perineum over the fecal matter (Goffe). The Levator ani is also a muscle of forced expiration.

The Coccygeus is a flat, triangular muscle situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising, by its apex, from the spine of the ischium, the obturator fascia, the edge of the great sacro-sciatic notch, and from the lesser sacro-sciatic ligament, and inserted, by its base, into the side of the lower two vertebrae of the sacrum and the upper two vertebrae of the coccyx. It assists the Levator ani and Pyriformis in closing in the back part of the outlet of the pelvis.

Relations.—By its inner or pelvic surface, with the rectum. By its external surface, with the lesser sacro-sciatic ligament. The lower border is in relation with the posterior border of the Levator ani, but separated from it by a cellular interval: its upper border is in relation with the lower border of the Pyriformis, but separated from it by the sciatic and internal pudic vessels and nerve.

Nerve-supply.—A branch from the fourth and fifth sacral nerves.

Action.—The Coccygei muscles raise and support the coccyx, after it has been pressed backward during defecation or parturition.

Transversus perinei superficialis. Erector penis.

Accelerator urinæ. Compressor urethrae.

Superficial Fascia (fascia superficialis perinei).—The superficial fascia of the perineum consists of two layers, superficial and deep, as in other regions of the body. The superficial fascia over the posterior portion of the perineum is arranged in fatty layers which fill the ischio-rectal fossa on each side of the rectum and anus. The superficial fascia over the anterior portion of the perineum (urethral region) requires fuller consideration.

The Superficial Layer is thick, loose, areolar in texture, and, except toward the scrotum, contains much adipose tissue in its meshes, the amount of which varies in different subjects. In front, it is continuous with the dartos of the scrotum; behind, it is continuous with the subcutaneous areolar tissue surrounding the anus; and, on either side, with the same fascia on the inner side of the thighs. In the middle line it is adherent to the skin of the raphé and to the deep layer of

---

1 Peter Thompson. The Myology of the Pelvic Floor.
the superficial fascia. This layer should be carefully removed after it has been
examined, when the deep layer will be exposed.

The Deep Layer of Superficial Fascia or the Fascia of Colles is thin, aponeurotic
in structure, and of considerable strength, serving to bind down the muscles of the
root of the penis. It is continuous, in front, with the deep fascia of the penis,
and the dartos of the scrotum, the fascia of the spermatic cord, and Scarpa's
fascia upon the anterior portion of the abdomen; on either side it is firmly
attached to the margins of the rami of the os pubis and ischium, external to
the crus penis, and as far back as the tuberosity of the ischium; posteriorly,
it curves down behind the Superficial transverse perineal muscles (reflected
portion of fascia) to join the lower margin of the triangular ligament, which
structure is a prolongation of the deep layer of the superficial fascia. The
depth layer is attached to the superficial layer in the median line and to the
median septum of the Accelerator urinae muscle. At the central tendon of the
perineum the reflected portion of the fascia becomes blended with the insertions
of the External anal sphincter, the two Superficial transverse perineal
muscles, and the Accelerator urinae. This fascia not only covers the muscles
in this region, but sends upward a vertical septum from its deep surface, which
separates the back part of the subjacent space into two, the septum being
incomplete in front.

The Central Tendinous Point of the Perineum.—This is a fibrous point in the
middle line of the perineum, between the urethra and the rectum, being about
half an inch in front of the anus. At this point four muscles converge and are
attached—viz., the External sphincter ani, the Accelerator urinae, and the two
Superficial transverse perineal; so that by the contraction of these muscles, which
extend in opposite directions, it serves as a fixed point of support.
The Transversus Perinei Superficialis is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and forepart of the tuberosity of the ischium, and, passing inward, is inserted into the central tendinous point of the perineum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Accelerator urinæ in front. The base of the triangular ligament lies just beneath this muscle.

**Nerve-supply.**—The perineal branch of the internal pudic.

**Actions.**—By their contraction they serve to fix the central tendinous point of the perineum.

The Accelerator Urinæ, called also the Ejaculator seminis and the Ejaculator urinæ (m. bulbocavernosus), is placed in the middle line of the perineum, immediately in front of the anus. It consists of two symmetrical halves, united along the median line by a tendinous raphé. It arises from the central tendon of the perineum, and from the median raphé in front. From this point its fibres diverge like the plumes of a pen; the most posterior form a thin layer, which is lost on the anterior surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis; the anterior fibres, the longest and most distinct, spread out over the sides of the corpus cavernosum, to be inserted partly into that body, anterior to the Erector penis, occasionally extending to the os pubis; partly terminating in a tendinous expansion, which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and dissecting it outward from the surface of the urethra. Many fibres of the External sphincter ani and of the Superficial transverse perineal muscles pass into this muscle.

**Action.**—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition.

---

![Figure 307](image-url)
its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed, by Krause, to assist in the erection of the corpus spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, on each side, which are known as Houston's muscles, according to Tyrrel, also contribute to the erection of the penis, as they are inserted into, and continuous with, the fascia of the penis, compressing the dorsal vein during the contraction of the muscle.

The Erector Penis (m. ischiocavernosus) covers part of the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perinaeum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis, from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

Nerve-supply.—The perineal branch of the internal pudic.

**Actions.**—It compresses the crus penis and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urine, externally by the Erector penis, and behind by the Transversus perinei superficialis. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forward in it are the superficial perineal vessels and nerves, the long pudendal nerve, and the transverse perineal artery coursing along the posterior boundary of the space on the Transversus perinei superficialis.

The Triangular Ligament or the Deep Perineal Fascia (trigonum or diaphragma urogenitale) (Figs. 305, 309, and 310) is stretched almost horizontally across the pubic arch, so as to close in the front part of the outlet of the pelvis. It con-
OF THE PERINEUM IN THE MALE

459

sists of two dense musculo-membranous laminae, which are united along their posterior borders, but are separated in front by intervening structures. The superficial of these two layers, the **superficial, anterior, or inferior layer** of the triangular ligament (*fascia trigoni urogenitalis inferior*), is triangular in shape and about an inch and a half in depth. Its apex is directed forward, and is separated from the subpubic ligament by an oval opening for the transmission of the dorsal vein of the penis. The apex of the triangular ligament is called the

**transverse perineal** or **transverse pelvic ligament** (*ligamentum transversum pelvis*). The lateral margins of the inferior layer of the triangular ligament are attached on each side to the rami of the ischium and os pubis, above the crura penis. The fusion of the two leaves posteriorly takes place beneath the Superficial transverse perineal muscles. The region of fusion of the two leaflets posteriorly is called the **base**. The base is directed toward the rectum, and connected to

the central tendinous point of the perineum. It is continuous with the deep layer of the superficial fascia behind the Superficial transverse perineal muscles, and with a thin fascia which covers the cutaneous surface of the Levator ani muscle, the **anal** or **ischio-rectal fascia**.

This layer of the triangular ligament is perforated, about an inch below the symphysis pubis, by the urethra, the aperture for which is circular in form and
about three or four lines in diameter; by the arteries to the bulb and the ducts of Cowper's glands close to the urethral orifice; by the arteries to the corpora cavernosa—one on each side, close to the pubic arch and about half-way along the attached margin of the ligament; by the dorsal arteries and nerves of the penis near the apex of the ligament. Its base is also perforated by the superficial perineal vessels and nerves, while between its apex and the subpubic ligament the dorsal nerve of the penis and the dorsal vein of the penis passes upward into the pelvis.

If this superficial or inferior layer of the triangular ligament is detached on either side, the following structures will be seen between it and the deeper layer: the dorsal vein of the penis; the membranous portion of the urethra, and the Compressor urethrae muscle; Cowper's glands and their ducts; the pudic vessels and dorsal nerve of the penis; the artery and nerve of the bulb, and a plexus of veins. The two layers join the urethral wall and vagina medianward.

The deep, posterior, or superior layer (fascia trigoni urogenitalis superior) of the triangular ligament is derived from the obturator fascia and stretches across the pubic arch. If the obturator fascia is traced inward after covering the Obturator internus muscle, it will be found to be attached by some of its deeper or anterior fibres to the inner margin of the ischio-pubic ramus, while its superficial or posterior fibres pass over this attachment to become the superior layer of the triangular ligament. Behind, this layer of the fascia is continuous with the inferior layer and with the fascia of Colles, and in front it is separated from the apex of the prostate gland through the intervention of a prolongation of the recto-vesical fascia. It is pierced by the urethra, or rather consists of two halves which are separated in the middle line by the urethra passing between them.

The Compressor or Constrictor Urethrae (m. constrictor urethrae) in the male surrounds the whole length of the membranous portion of the urethra, and is contained between the two layers of the triangular ligament. It arises, by apon-eurotic fibres, from the junction of the rami of the os pubis and ischium, to the extent of half or three-quarters of an inch: the point where the crura penis joins the transverse ligament of the perineum and the layers of the triangular ligament; each segment of the muscle passes inward, and divides into two fasciculi, which surround the membranous urethra and unite, at the upper and lower surfaces of this tube, with the muscle of the opposite side by means of a tendinous raphé. The Compressor urethrae is continuous posteriorly with the m. prostaticus and is continuous anteriorly with the circular fibres of the cavernous portion of the urethra. This muscle is frequently in two portions, an anterior and a posterior, separated by a distinct interval. In such cases the posterior fibres are called the transversus perinei profundus, and the anterior fibres are called the sphincter urethrae membranae.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the Acceleratores urine, are relaxed, and come into action only at the end of the process, to eject the last drops of the fluid.

3. The Muscles of the Perineum in the Female (Fig. 311).

Transversus perinei superficialis.
Sphincter vaginae.

Erector clitoridis.
Compressor urethrae.

The Transversus Perinei Superficialis in the female is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space.
It arises by a small tendon from the inner and forepart of the tuberosity of the ischium, and, passing inward, is inserted into the central point of the perineum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Sphincter vaginae in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perineum.

The Sphincter Vaginae (m. bulbocavernosus) surrounds the orifice of the vagina, and is analogous to the Accelerator urinæ in the male. It is attached posteriorly to the central tendinous point of the perineum, where it blends with the External sphincter ani. Its fibres pass forward on each side of the vagina, to be inserted into the corpora cavernosa of the clitoris, a fasciculus crossing over the body of the organ so as to compress the dorsal vein.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris; compressing the dorsal vein during the contraction of the muscle.

The Erector Clitoridis (m. ischiocavernosus) resembles the Erector penis in the male, but is smaller than it. It covers the unattached part of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on either side of the lateral boundary of the perineum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed,
which end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

_Nerve-supply._—The perineal branch of the internal pudic.

_Actions._—It compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The **Triangular Ligament** (*trigonum urogenitale*) in the female is not so strong as in the male. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the Transversus perinei muscle.

Like the triangular ligament in the male, it consists of two layers, between which are to be found the following structures: the dorsal vein of the clitoris, a portion of the urethra and the Compressor urethrae muscle, the glands of Bartholin and their ducts; the pudic vessels and the dorsal nerve of the clitoris; the arteries of the bulb vestibuuli, and a plexus of veins.

The **Compressor Urethrae** (*m. constrictor urethrae*) arises on each side from the margin of the descending ramus of the os pubis. The fibres, passing inward, divide into two sets: those of the forepart of the muscle are directed across the subpubic arch in front of the urethra to blend with the muscular fibres of the opposite side; while those of the hinder and larger part pass inward to blend with the wall of the vagina behind the urethra.

_Nerve-supply._—The perineal branch of the internal pudic.

Dissection of Pectoral Region and Axilla (Fig. 312).—The arm being drawn away from the side nearly at right angles with the trunk and rotated outward, make a vertical incision through the integument in the median line of the chest, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoral muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downward, along the interspace between the Pectoral and Deltoid muscles, as low as the fold of the armpit. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed, as it should be replaced on completing the dissection. If a transverse incision is now made from the lower end of the sternum to the side of the chest, as far as the posterior fold of the armpit, and the integument reflected outward, the axillary space will be more completely exposed.

I. THE MUSCLES AND FASCIÆ OF THE THORACIC REGION.

1. The Anterior Thoracic Region.

Pectoralis major. 
Subclavius.

Pectoralis minor.

Superficial Fascia.—The superficial fascia of the thoracic region is a loose cellulo-fibrous layer enclosing masses of fat in its spaces. It is continuous with the superficial fascia of the neck and upper extremity above, and of the abdomen below. Opposite the mamma it divides into two layers, one of which passes in front, the other behind, that gland; and from both of these layers numerous septa pass into its substance, supporting its various lobes: from the anterior layer fibrous processes pass forward to the integument and nipple. These processes were called by Sir A. Cooper the suspensory ligaments (ligamenta suspensoria), from the support they afford to the gland in this situation.

Deep Fascia.—The deep thoracic fascia is a thin aponeurotic lamina, covering the surface of the great Pectoral muscle, and sending numerous prolongations between its fasciculi: it is attached, in the middle line, to the front of the sternum, and above to the clavicle; externally and below it becomes continuous with the fascia over the shoulder, axilla, and thorax. It is very thin over the upper part of the muscle, thicker in the interval between the Pectoralis major and Latissimus dorsi, where it closes in the axillary space, and is known as the axillary fascia (fascia axillaris). It passes behind into the fascia of the Latissimus dorsi and Teres major, in front into the fascia of the deltoid and outward into the brachial fascia. The fascia of the Latissimus dorsi divides at the outer margin of the muscle into two layers, one of which passes in front and the other behind it; these proceed as far as the spinous processes of the dorsal vertebrae, to which they are
attached. As the axillary fascia leaves the lower edge of the Pectoralis major to pass across the floor of the axilla it sends a layer upward under cover of the muscle, **deep pectoral fascia**: this lamina splits to envelop the Pectoralis minor, at the upper edge of which it becomes continuous with the **costo-coracoid membrane**, or the **clavi-pectoral fascia**. The hollow of the armpit, seen when the arm is abducted, is mainly produced by the traction of this fascia on the axillary floor, the **axillary fascia** (fascia axillaris), and hence it is sometimes named the **suspensory ligament of the axilla**. The axillary fascia (Fig. 313) is not a distinct and complete rigid floor of the axillary space. Like all other fasciae, it follows muscular planes, and splits to encompass vessels, nerves, and muscles. In it are numerous perforations. In this fascia is a curved arch which often contains muscular fibres and which passes from the tendon of the great Pectoral,

---

**Fig. 312.—Dissection of upper extremity.**

---

the Coraco-brachialis or the fascia over the biceps to the tendon of the Latissimus dorsi. This is called the **axillary arch**. Langer showed many years ago that there is an opening in the centre of the dense axillary fascia, the **foramen of Langer**. Through this opening axillary glands not unusually protrude. The axillary arch is the inner margin of the foramen of Langer. At the lower part of the thoracic region the deep thoracic fascia is well developed, and is continuous with the fibrous sheath of the Recti muscles.

The **Pectoralis Major** (Fig. 314) is a broad, thick, triangular muscle, situated at the upper and forepart of the chest, in front of the axilla. It **arises** from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; this portion of its origin consists of aponeurotic fibres, which intersect with those of the opposite muscle; it also arises from the carpi-
lages of all true ribs, with the exception, frequently, of the first or of the seventh, or both; and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge toward its insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outward and downward and are usually separated from the rest by a cellular interval: those from the lower part of the sternum, and the cartilages of the lower true ribs, pass upward and outward, whilst the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches broad, which is inserted into the outer bicipital ridge of the humerus. This tendon consists of two laminae, placed one in front of the other, and usually blended together below. The anterior, the thicker, receives the clavicular and upper half of the sternal portion of the muscle; and its fibres are inserted in the same order as that in which they arise; that is to say, the outermost fibres of origin from the clavicle are inserted at the uppermost part of the tendon; the upper fibres of origin from the sternum pass down to the lowermost part of this anterior lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The posterior lamina of the tendon receives the attachment of the lower half of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend, the higher, turning backward successively behind the superficial and upper ones, so that the tendon appears to be twisted. The posterior lamina reaches higher on the humerus than does the anterior one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the bicipital groove of the humerus, while from the lower border of the tendon a third expansion passes downward to the fascia of the arm. Between the poste-
rior surface of the tendon of the great pectoral and the anterior surface of the long head of the biceps there is usually a bursa (*bursa m. pectoralis majoris*).

**Relations.**—By its *anterior surface*, with the integument, the superficial fascia, the Platysma, some of the branches of the descending cervical nerves, the mammary gland, and the deep fascia; by its *posterior surface*: its *thoracic portion*, with the sternum, the ribs and costal cartilages, the costo-coracoid membrane, the Subclavius, Pectoralis minor, Serratus magnus, and the Intercostals; its *axillary por-

![Figure 314](image)

**Fig. 314.**—Muscles of the chest and front of the arm. Superficial view.

tion forms the anterior wall of the axillary space, and covers the axillary vessels and nerves, the Biceps and Coraco-brachialis muscles. Its *upper border* lies parallel with the Deltoid, from which it is separated by a slight interspace in which lie the cephalic vein and humeral branch of the acromial thoracic artery. Its *lower border* forms the anterior margin of the axilla, being at first separated from the Latissimus dorsi by a considerable interval; but both muscles gradually converge toward the outer part of the space.
Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to its line of attachment to the sternum and costal cartilages. The muscle should then be reflected outward, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the costo-coracoid membrane.

The **Costo-coracoid Membrane** or the **Clavipectoral Fascia** is a strong fascia, situated under cover of the clavicular portion of the Pectoralis major muscle. It occupies the interval between the Pectoralis minor and Subclavius muscle, and protects the axillary vessels and nerves. Traced upward, it splits to enclose the Subclavius muscle, and its two layers are attached to the clavicle, one in front of and the other behind the muscle; the latter layer fuses with the deep cervical fascia and with the sheath of the axillary vessels. Internally, it blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib internal to the origin of the Subclavius muscle. Externally it is very thick and dense, and is attached to the coracoid process. The portion extending from its attachment to the first rib to the coracoid process is often whiter and denser than the rest; this is sometimes called the **costo-coracoid ligament**. Below, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle; from the lower border of the Pectoralis minor it is continued downward to join the axillary fascia, and outward to join the fascia over the short head of the Biceps. The costo-coracoid membrane is pierced by the cephalic vein, the acromial thoracic artery and vein, superior thoracic artery, and anterior thoracic nerves.
The Pectoralis Minor (Fig. 315) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises by three tendinous digitations from the upper margin and outer surface of the third, fourth, and fifth ribs, near their cartilages, and from the aponeurosis covering the intercostal muscles; the fibres pass upward and outward, and converge to form a flat tendon, which is inserted into the inner border and upper surface of the coracoid process of the scapula.

Relations.—By its anterior surface, with the Pectoralis major and the thoracic branches of the acromial thoracic artery. By its posterior surface, with the ribs, intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and brachial plexus of nerves. Its upper border is separated from the clavicle by a triangular interval, broad internally, narrow externally, which is occupied by the costo-coracoid membrane. This space contains the first part of the axillary vessels and the axillary nerves. Running parallel to the lower border of the muscle is the long thoracic artery.

The costo-coracoid membrane should now be removed, when the Subclavius muscle will be seen.

The Subclavius is a small triangular muscle, placed in the interval between the clavicle and the first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the rhomboid ligament; the fleshy fibres proceed obliquely upward and outward, to be inserted into a deep groove on the under surface of the clavicle. An extension from the aponeurosis of this muscle lies upon the subclavian vein.

Relations.—By its upper surface, with the clavicle. By its deep surface it is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its anterior surface is separated from the Pectoralis major by the costo-coracoid membrane, which, with the clavicle, forms an osseo-fibrous sheath in which the muscle is enclosed.

If the costal attachment of the Pectoralis minor is divided across, and the muscle reflected outward, the axillary vessels and nerves are brought fully into view, and should be examined.

Nerves.—The Pectoral muscles are supplied by the anterior thoracic nerves; the Pectoralis major through these nerves receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the eighth cervical and first dorsal nerves. The Subclavius is supplied by a filament from the fifth cervical nerve.

Actions.—If the arm has been raised by the Deltoid, the Pectoralis major will, jointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forward the arm, bringing it across the front of the chest, and at the same time rotates it inward. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downward and inward to the thorax, and throwing the inferior angle backward. The Subclavius depresses the shoulder, drawing the clavicle downward and forward. When the arms are fixed, all three muscles act upon the ribs, drawing them upward and expanding the chest, and thus becoming very important agents in forced inspiration. Asthmatic patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in dilating the cavity of the chest.

2. The Lateral Thoracic Region.

Serratus magnus.

The Serratus Magnus (m. serratus anterior) (Figs. 315 and 316) is a thin, irregularly quadrilateral muscle, situated between the ribs and the scapula at the upper
and lateral part of the chest. It arises by nine digitations or slips from the outer surface and upper border of the eight upper ribs (the second rib giving origin to two slips), and from the aponeurosis covering the corresponding intercostal muscles. From this extensive attachment the fibres pass backward, closely applied to the chest-wall, and reach the vertebral border of the scapula, and are inserted into its ventral aspect in the following manner. The upper two digitations—i.e., the one from the first rib and the higher of the two from the second rib—converge to be inserted into a triangular area on the ventral aspect of the superior angle. The next two digitations spread out to form a thin triangular sheet, the base of which is directed backward and is inserted into nearly the whole length of the ventral aspect of the vertebral border. The lower five digitations converge, as they pass backward from the ribs, to form a fan-shaped structure, the apex of which is inserted, partly by muscular and partly by tendinous fibres, into a triangular impression on the ventral aspect of the inferior angle. The lower four slips interdigitate at their origin with the upper five slips of the External oblique muscle of the abdomen.

Relations.—This muscle is partly covered, in front, by the Pectoral muscles; behind, by the Subscapularis. The axillary vessels and nerves lie upon its upper part, while its deep surface rests upon the ribs and intercostal muscles.

Nerve.—The Serratus magnus is supplied by the posterior thoracic nerve, which is derived from the fifth, sixth, and generally the seventh cervical nerves.

Actions.—The Serratus magnus, as a whole, carries the scapula forward, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forward the lower angle and assist the Trapezius in rotating the bone round an axis through its centre, and thus assists this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoid in raising the arm, insomuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus rotates. After the Deltoid has raised the arm to a right angle with the trunk, the Serratus magnus and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus magnus may assist in raising and evertting the ribs; but it is not the important inspiratory muscle which it was formerly believed to be.

Surgical Anatomy.—When the muscle is paralyzed, the vertebral border, and especially the lower angle of the scapula, leaves the ribs and stands out prominently on the surface, giving a peculiar "winged" appearance to the back. The patient is unable to raise the arm, and an
THE MUSCLES AND FASCIAE

II. MUSCLES AND FASCIAE OF THE SHOULDER AND ARM.

Superficial Fascia.—The superficial fascia of the upper extremity is a thin cellulo-fibrous layer, containing the superficial veins and lymphatics, and the cutaneous nerves: It is most distinct in front of the elbow, and contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Small subcutaneous bursae are found in this fascia over the acromion, the olecranon, and the knuckles.

Deep Fascia.—The deep fascia of the upper extremity comprises the aponeurosis of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

3. The Acromial Region.

Deltoid.

Deep Fascia.—The deep fascia covering the Deltoid, and known as the deltoid aponeurosis, is a fibrous layer which covers the outer surface of the muscle, thick and strong behind, where it is continuous with the infraspinatus fascia, thinner over the rest of its extent. It sends down numerous prolongations between the fasciculi of the muscle. In front, it is continuous with the fascia covering the great Pectoral muscle; behind, with that covering the Infraspinatus; above, it is attached to the clavicle, the acromion, and spine of the scapula; below, it is continuous with the deep fascia of the arm.

The Deltoid (m. deltoideus) (Fig. 314) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Δ reversed. It surrounds the shoulder-joint in the greater part of its extent, covering it on its outer side, and in front and behind. It arises from the outer third of the anterior border and upper surface of the clavicle; from the outer margin and upper surface of the acromion process, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its inner end. From this extensive origin the fibres converge toward their insertion, the middle passing vertically, the anterior obliquely backward, the posterior obliquely forward; they unite to form a thick tendon, which is inserted into a rough triangular prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its muscular fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of oblique fibres, which arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downward parallel to one another in the substance of the muscle.
oblique muscular fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upward from the insertion of the muscle into the humerus and alternate with the descending septa. The portions of the muscle which arise from the clavicle and spine of the scapula are not arranged in this manner, but pass from their origin above, to be inserted into the margins of the inferior tendon.

Relations.—By its superficial surface, with the integument, the superficial and deep fasciae, Platysma, and supra-acromial nerves. Its deep surface is separated from the head of the humerus by a large sacculated synovial bursa, the subdeltoid bursa (bursa subdeltoididea). It often communicates with the subacromial bursa (bursa subacromialis), which is between the acromial process and the coraco-acromial ligament above and the capsule of the shoulder-joint and the Supraspinatus muscle below. The deep surface of the deltoid covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coraco-brachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the humerus. Its anterior border is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and humeral branch of the acromial thoracic artery; lower down the two muscles are in close contact. Its posterior border rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoid is supplied by the fifth and sixth cervical through the circumflex nerve.

Actions.—The Deltoid raises the arm directly from the side, so as to bring it at right angles with the trunk, but this act cannot be performed without the aid of the Serratus magnus, which muscle steadies the lower angle of the scapula. Its anterior fibres, assisted by the Pectoralis major, draw the arm forward; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backward.

Surgical Anatomy.—The Deltoid is very liable to atrophy, and when in this condition simulates dislocation of the shoulder-joint, as there is flattening of the shoulder and apparent prominence of the acromion process; upon examination, however, it will be found that the relative position of the great tuberosity of the humerus to the acromion and coracoid process is unchanged. Atrophy of the Deltoid may be due to disuse or loss of trophic influence, either from injury to the circumflex nerve or cord lesions, as in infantile paralysis.

4. The Anterior Scapular Region.

Subscapularis.

Dissection.—Divide the Deltoid across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process and spine of the scapula, and reflect it downward, when the structures under cover of it will be seen.

The Subscapular Fascia (fascia subscapularis).—The subscapular fascia is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle: when this is removed, the Subscapularis muscle is exposed.

The Subscapularis (Fig. 315) is a large triangular muscle which fills up the subscapular fossa, arising from its internal two-thirds, with the exception of a narrow margin along the posterior border, and the surfaces at the superior and inferior angles which afford attachment to the Serratus magnus: it also arises from the lower two-thirds of the groove on the axillary border of the bone. Some fibres arise from tendinous laminae, which intersect the muscle, and are attached to ridges on the bone; and others from an aponeurosis, which separates the muscles from the Teres major and the long head of the Triceps. The fibres pass outward, and, gradually converging, terminate in a tendon, which is inserted into the lesser
tuberosity of the humerus. Those fibres which arise from the axillary border of the scapula are inserted into the neck of the humerus to the extent of an inch below the tuberosity. The tendon of the muscle is in close contact with the anterior part of the capsular ligament of the shoulder-joint, and glides over a large bursa, the **bursa of the subscapularis muscle** (*bursa m. subscapularis*, which separates it from the base of the coracoid process. This bursa communicates with the cavity of the joint by an aperture in the capsular ligament.

**Relations.**—Its **anterior surface** forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus magnus, Coraco-brachialis, and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. By its **posterior surface**, with the scapula and the capsular ligament of the shoulder-joint. Its **lower border** is contiguous with the Teres major and Latissimus dorsi.

**Nerves.**—It is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

**Actions.**—The Subscapularis rotates the head of the humerus inward; when the arm is raised, it draws the humerus forward and downward. It is a powerful defence to the front of the shoulder-joint, preventing displacement of the head of the bone.

5. The Posterior Scapular Region (Fig. 317).

**Dissection.**—To expose these muscles, and to examine their mode of insertion into the humerus, detach the deltoid and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula: divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed, and can be examined. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

The **Supraspinatus Fascia** (*fascia supraspinata*).—The supraspinatus fascia is a thick and dense membranous layer, which completes the osseo-fibrous case in which the Supraspinatus muscle is contained, affording attachment, by its inner surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament. When this fascia is removed, the Supraspinatus muscle is exposed.

The **Supraspinatus Muscle** occupies the whole of the supraspinatus fossa, arising from its internal two-thirds and from the strong fascia which covers its surface. The muscular fibres converge to a tendon which passes across the upper part of the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is inserted into the highest of the three facets on the great tuberosity of the humerus.

**Relations.**—By its **upper surface**, with the Trapezius, the clavicle, the acromion, the coraco-acromial ligament, and the Deltoid; by its **under surface**, with the scapula, the suprascapular vessels and nerve, and upper part of the shoulder-joint.

The **Infraspinatus Fascia** (*fascia infraspinata*).—The infraspinatus fascia is a dense fibrous membrane, covering in the Infraspinatus muscle and attached to the circumference of the infraspinatus fossa; it affords attachment, by its inner surface, to some fibres of that muscle. At the point where the Infraspinatus commences to be covered by the Deltoid, this fascia divides into two layers: one layer passes over the Deltoid muscle, helping to form the Deltoid fascia already described; the other passes beneath the Deltoid to the capsule of the shoulder-joint.

The **Infraspinatus** is a thick, triangular muscle, which occupies the chief part of the infraspinatus fossa, arising by fleshy fibres from its internal two-thirds, and
by tendinous fibres from the ridges on its surface: it also arises from a strong fascia which covers it externally, and separates it from the Teres major and minor. The fibres converge to a tendon which glides over the external border of the spine of the scapula, and, passing across the posterior part of the capsular ligament of the shoulder-joint, is inserted into the middle facet on the great tuberosity of the humerus. The tendon of this muscle has interposed between it and the joint capsule a synovial bursa, the **bursa of the Infraspinatus muscle** (*bursa m. infraspinati*), which communicates with the synovial cavity of the shoulder-joint.

**Relations.**—By its *posterior surface*, with the Deltoid, the Trapezius, Latissimus dorsi, and the integument; by its *anterior surface*, with the scapula, from which it is separated by the suprascapular and dorsalis scapulae vessels, and with the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres minor, occasionally united with it, and with the Teres major.

The **Teres Minor** is a narrow, elongated muscle, which *arises* from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminae, one of which separates this muscle from the Infraspinatus, the other from the Teres major; its fibres pass obliquely upward and outward, and terminate in a tendon which is *inserted* into the lowest of the three facets on the great tuberosity of the humerus, and, by fleshy fibres, into the humerus immediately below it. The tendon of this muscle passes across the posterior part of the capsular ligament of the shoulder-joint.

**Relations.**—By its *posterior surface*, with the Deltoid and the integument; by its *anterior surface*, with the scapula and dorsal branch of the subscapular artery, the long head of the Triceps, and the shoulder-joint; by its *upper border,*
with the Infraspinatus; by its lower border, with the Teres major, from which it is separated anteriorly by the long head of the Triceps.

The Teres Major is a thick but somewhat flattened muscle, which arises from the oval surface on the dorsal aspect of the inferior angle of the scapula, and from the fibrous septa interposed between it and the Teres minor and Infraspinatus; the fibres are directed upward and outward, and terminate in a flat tendon, about two inches in length, which is inserted into the inner bicipital ridge of the humerus. The tendon of this muscle, at its insertion into the humerus, lies behind that of the Latissimus dorsi, from which it is separated by a synovial bursa, the bursa of the Latissimus dorsi muscle (bursa m. latissimi dorsi), the two tendons being, however, united along their lower borders for a short distance. Between the tendon of the Teres major and the bone is the bursa m. teretis majoris.

Relations.—By its posterior surface, with the Latissimus dorsi below, and the long head of the Triceps above. By its anterior surface, with the Subscapularis, Latissimus dorsi, Coraco-brachialis, short head of the Biceps, the axillary vessels, and brachial plexus of nerves. Its upper border is at first in relation with the Teres minor, from which it is afterward separated by the long head of the Triceps. Its lower border forms, in conjunction with the Latissimus dorsi, part of the posterior boundary of the axilla. The Latissimus dorsi at first covers the origin of the Teres major, then wraps itself obliquely round its lower border, so that its tendon ultimately comes to lie in front of that of the Teres major.

Nerves.—The Supra- and Infraspinatus muscles are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the Teres minor, by the fifth cervical, through the circumflex; and the Teres major, by the fifth and sixth cervical, through the lower subscapular.

Actions.—The Supraspinatus assists the Deltoid in raising the arm from the side, and fixes the head of the humerus in the glenoid cavity. The Infraspinatus and Teres minor rotate the head of the humerus outward: when the arm is raised, they assist in retaining it in that position and carrying it backward. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the Supraspinatus supporting it above, and preventing displacement of the head of the humerus upward, while the Infraspinatus and Teres minor protect it behind, and prevent dislocation backward. The Teres major assists the Latissimus dorsi in drawing the humerus downward and backward, when previously raised, and rotating it inward; when the arm is fixed, it may assist the Pectoral and Latissimus dorsi muscles in drawing the trunk forward.

THE MUSCLES AND FASCIAE OF THE ARM.

6. The Anterior Humeral Region (Fig. 315).

Dissection.—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the clavicle to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (Fig. 312).

Deep Fascia (fascia brachii).—The deep fascia of the arm is continuous with that covering the Deltoid and the great Pectoral muscles, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula, and is also continuous with the axillary fascia. It forms a thin, loose, membranous sheath investing the muscles of the arm, sending down septa between them, and composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being
thin over the Biceps, but thicker where it covers the Triceps, and over the condyles of the humerus; it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi on the inner side, and from the Deltoid externally. On either side it gives off a strong intermuscular septum, which is attached to the supracondylar ridge and condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The external intermuscular septum (septum intermusculare laterale) extends from the lower part of the anterior bicipital ridge, along the external supracondylar ridge, to the outer condyle; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis anticus, Supinator longus, and Extensor carpi radialis longior, in front, and is perforated by the musculo-spiral nerve and superior profunda artery. The internal intermuscular septum (septum intermusculare mediale), thicker than the preceding, extends from the lower part of the posterior lip of the bicipital groove below the Teres major, along the internal supracondylar ridge to the inner condyle; it is blended with the tendon of the Coraco-brachialis, and affords attachment to the Triceps behind, and the Brachialis anticus in front. It is perforated by the ulnar nerve and the inferior profunda and anastomotic arteries. At the elbow the deep fascia is attached to all the prominent points round the joint—viz., the condyles of the humerus and the olecranon process of the ulna—and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the intermuscular septum, is an oval opening in the deep fascia which transmits the basilic vein and some lymphatic vessels. On the removal of this fascia the muscles, vessels, and nerves of the anterior humeral region are exposed.

The Coraco-brachialis, the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum between the two muscles; the fibres pass downward, backward, and a little outward, to be inserted by means of a flat tendon into an impression at the middle of the inner surface and internal border of the shaft of the humerus between the origins of the Triceps and Brachialis anticus. It is perforated by the musculo-cutaneous nerve. The inner border of the muscle forms a guide to the position of the brachial artery in tying the vessel in the upper part of its course. Between the tendon of the subscapularis, the coracoid process and the tendon of the Coraco-brachialis, is the bursa of the Coraco-brachialis muscle (bursa m. coracobrachialis).

Relations.—By its anterior surface, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it; by its posterior surface, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the humerus, and the anterior circumflex vessels; by its inner border, with the brachial artery, and the median and musculo-cutaneous nerves; by its outer border, with the short head of the Biceps and Brachialis anticus.

The Biceps or the Biceps Flexor Cubiti (m. biceps brachii) is a long fusiform muscle, occupying the whole of the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The short head (caput breve) arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coraco-brachialis. The long head (caput longum) arises from the upper margin of the glenoid cavity, and is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by a fibrous prolongation from the tendon of the Pectoralis major. Each tendon is succeeded by an
elongated muscular belly, and the two bellies, although closely applied to each other, can readily be separated until within about three inches of the elbow-joint. Here they end in a flattened tendon, which is inserted into the back part of the tuberosity of the radius, a synovial bursa (bursa bicipito-radialis), being interposed between the tendon and the front of the tuberosity, and another bursa (bursa cubitalis interossea) is often interposed between the ulna and the tendon. As the tendon of the muscle approaches the radius it becomes twisted upon itself, so that its anterior surface becomes external and is applied to the tuberosity of the radius at its insertion: opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the bicipital or semilunar fascia (lacertus fibrosus), which passes obliquely downward and inward across the brachial artery, and is continuous with the deep fascia of the forearm (Fig. 314). The inner border of this muscle forms a guide to the position of the vessel in tying the brachial artery in the middle of the arm.1

Relations.—Its anterior surface is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciae and the integument. Its posterior surface rests above on the shoulder-joint and upper part of the humerus; below it rests on the Brachialis anticus, with the musculo-cutaneous nerve intervening between the two, and on the Supinator brevis. Its inner border is in relation with the Coraco-brachialis, and overlaps the brachial vessels and median nerve; its outer border, with the Deltoid and Supinator longus.

The Brachialis Anticus (m. brachialis) is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backward, and is broader in the middle than at either extremity. It arises from the lower half of the outer and inner surfaces of the shaft of the humerus, and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below, to within an inch of the margin of the articular surface, and is limited on each side by the external and internal borders of the shaft of the humerus. It also arises from the intermuscular septa on each side, but more extensively from the inner than the outer, from which it is separated below by the Supinator longus and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is inserted into a rough depression on the anterior surface of the coronoid process of the ulna, being received into an interval between two fleshy slips of the Flexor profundus digitorum.

Relations.—By its anterior surface, with the Biceps, the brachial vessels, musculo-cutaneous, and median nerves; by its posterior surface, with the humerus and front of the elbow-joint; by its inner border, with the Triceps, ulnar nerve, and Pronator radii teres, from which it is separated by the intermuscular septum; by its outer border, with the musculo-spiral nerve, radial recurrent artery, the Supinator longus, and Extensor carpi radialis longior.

Nerves.—The muscles of this group are supplied by the musculo-cutaneous nerve. The Brachialis anticus usually receives an additional filament from the musculo-spiral. The Coraco-brachialis receives its supply primarily from the seventh cervical, the Biceps and Brachialis anticus from the fifth and sixth cervical nerves.

Actions.—The Coraco-brachialis draws the humerus forward and inward, and at the same time assists in elevating it toward the scapula. The Biceps is a flexor of the forearm; it is also a powerful supinator, and serves to render tense the deep fascia of the forearm by means of the broad aponeurosis given off from

1 A third head to the Biceps is occasionally found (Theile says as often as once in eight or nine subjects), arising at the upper and inner part of the Brachialis anticus, with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. Occasionally the third head consists of two slips which pass down, one in front, the other behind the artery, concealing the vessel in the lower half of the arm.
its tendon. The Brachialis anticus is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps and Brachialis anticus flex the arm upon the forearm, as is seen in efforts at climbing.

7. The Posterior Humeral Region.

Triceps. Subbancaneous.

The Triceps or the Triceps Extensor Cubiti (m. triceps brachii) (Fig. 317) is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and divided above into three parts; hence its name. These three portions have been named (1) the middle, scapular, or long head; (2) the external or long humeral head; and (3) the internal or short humeral head.

The Middle, Long, or Scapular Head (caput longum) arises, by a flattened tendon, from a rough triangular depression on the scapula, immediately below the glenoid cavity, being blended at its upper part with the capsular ligament; the muscular fibres pass downward between the two other portions of the muscle, and join with them in the common tendon of insertion.

The External Head (caput laterale) arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculo-spiral groove; from the external border of the humerus and the external intermuscular septum: the fibres from this origin converge toward the common tendon of insertion.

The Internal Head (caput mediale) arises from the posterior surface of the shaft of the humerus, below the groove for the musculo-spiral nerve; commencing above, narrow and pointed, below the insertion of the Teres major, and extending to within an inch of the trochlear surface: it also arises from the internal border of the humerus, and from the back of the whole length of the internal and lower part of the external intermuscular septum. The fibres of this portion of the muscle are directed, some downward to the olecranon, whilst others converge to the common tendon of insertion.

The Common Tendon of the Triceps commences about the middle of the back part of the muscle: it consists of two aponeurotic laminae, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent; the other is more deeply seated in the substance of the muscle: after receiving the attachment of the muscular fibres, they join together above the elbow, and are inserted, for the most part, into the back part of the upper surface of the olecranon process; a band of fibres is, however, continued downward, on the outer side, over the Anconeus, to blend with the deep fascia of the forearm. A small bursa (bursa subdeltidea olecrani) occasionally multilocular, is situated on the front part of this surface, beneath the tendon. The subcutaneous olecranon bursa (bursa subcutanea olecrani) is situated between the olecranon process and the skin. Within the tendon of the triceps is often found the bursa intrartidea olecrani.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (Fig. 317). The triangular space contains the dorsalis scapulae vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps externally: the quadrangular space transmits the posterior circumflex vessels and the circumflex nerve; it is bounded by the Teres minor above, the Teres major below, the scapular head of the Triceps internally, and the humerus externally.

Relations.—By its posterior surface, with the Deltoid above: in the rest of its extent it is subcutaneous; by its anterior surface, with the humerus, musculo-spiral nerve, superior profunda vessels, and back part of the elbow-joint. Its
middle or long head is in relation, behind, with the Deltoid and Teres minor; in front, with the Subscapularis, Latissimus dorsi, and Teres major.

The Subanconeus (m. anconeus) is a name given to a few fibres from the under surface of the lower part of the Triceps muscle, which are inserted into the posterior ligament of the elbow-joint. By some authors it is regarded as the analogue of the Subcrureus in the lower limb, but it is not a separate muscle.

Nerves.—The Triceps is supplied by the seventh and eighth cervical nerves through the musculo-spiral nerve.

Actions.—The Triceps is the great extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the Biceps and Brachialis anticus. When the arm is extended the long head of the muscles may assist the Teres major and Latissimus dorsi in drawing the humerus backward and in adducting it to the thorax. The long head of the Triceps protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downward and backward. The Subanconeus draws up the posterior ligament during extension of the forearm.

Surgical Anatomy.—The existence of the band of fibres from the Triceps to the fascia of the forearm is of importance in excision of the elbow, and should always be carefully preserved from injury by the operator, as by means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity; that is to say, allowing the forearm to drop from its own weight.

III. MUSCLES AND FASCIAE OF THE FOREARM.

Dissection.—To dissect the forearm, place the limb in the position indicated in Fig. 312, make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

Deep Fascia (fascia antibrachii).—The deep fascia of the forearm, continuous above with that enclosing the arm, is a dense, highly glistening aponeurotic investment, which forms a general sheath enclosing the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and gives off from its inner surface numerous intermuscular septa, which enclose each muscle separately. Below, it is continuous in front with the anterior annular ligament (ligamentum carpi volare), and forms a sheath for the tendon of the Palmaris longus muscle, which passes over the annular ligament to be inserted into the palmar fascia. Behind, near the wrist-joint, it becomes much thickened by the addition of many transverse fibres, and forms the posterior annular ligament (ligamentum carpi dorsale). It consists of circular and oblique fibres, connected together by numerous vertical fibres. It is much thicker on the dorsal than on the palmar surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Brachialis anticus and Biceps in front, and from the Triceps behind. Its deep surface gives origin to muscular fibres, especially at the upper part of the inner and outer sides of the forearm, and forms the boundaries of a series of conical-shaped cavities, in which the muscles are contained. Besides the vertical septa separating each muscle, transverse septa are given off on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layer of muscles. Numerous apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins.

The muscles of the forearm may be subdivided into groups corresponding to the region they occupy. One group occupies the inner and anterior aspect of the forearm, and comprises the Flexor and Pronator muscles. Another group occupies its outer side, and a third its posterior aspect. The two latter groups include all the Extensor and Supinator muscles.
8. The Anterior Radio-ulnar Region.

The muscles in this region are divided for convenience of description into two groups or layers, superficial and deep.

The Superficial Layer.

Pronator radii teres.
Flexor carpi radialis.
Flexor sublimis digitorum.
Palmaris longus.
Flexor carpi ulnaris.

These muscles take origin from the internal condyle of the humerus by a common tendon.

The Pronator Radii Teres (m. pronator teres) arises by two heads. One, the larger and more superficial, humeral head (caput humerale), arises from the humerus, immediately above the internal condyle, and from the tendon common to the origin of the other muscles; also from the fascia of the forearm and the intermuscular septum between it and the Flexor carpi radialis. The other head, the ulnar head (caput ulnare), is a thin fasciculus which arises from the inner side of the coronoid process of the ulna, joining the preceding at an acute angle. Between the two heads the median nerve enters the forearm. The muscle passes obliquely across the forearm from the inner to the outer side, and terminates in a flat tendon, which turns over the outer margin of the radius, and is inserted into a rough impression at the middle of the outer surface of the shaft of that bone.

Relations.—By its anterior surface, throughout the greater part of its extent, with the deep fascia; at its insertion it is crossed by the radial vessels and nerve, and is covered by the Supinator longus; by its posterior surface, with the Brachialis anticus, Flexor sublimis digitorum, the median nerve, and ulnar artery, the small or deep head being interposed between the two latter structures. Its outer border forms the inner boundary of a triangular space in which are placed the brachial artery, median nerve, and tendon of the Biceps muscle. Its inner border is in contact with the Flexor carpi radialis.

Surgical Anatomy.—This muscle, when suddenly brought into very active use, as in the game of lawn tennis, is apt to be strained, producing slight swelling and tenderness, and pain on putting the muscle into action. This is known as lawn-tennis arm.

The Flexor Carpi Radialis lies on the inner side of the preceding muscle. It arises from the internal condyle by the common tendon, from the fascia of the forearm, and from the intermuscular septa between it and the Pronator radii teres, on the outside, the Palmaris longus internally, and the Flexor sublimis digitorum beneath. Slender and aponeurotic in structure at its commencement, it increases in size, and terminates in a tendon which forms rather more than the lower half of its length. This tendon passes through a canal on the outer side of the annular ligament, runs through a groove in the os trapezium (which is converted into a canal by a fibrous sheath, and is lined by a synovial membrane), and is inserted into the base of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger. The radial artery lies between the tendon of this muscle and the Supinator longus, and may easily be tied in this situation. In the hand a bursa (bursa m. flexoris carpi radialis) lies between the base of the second metacarpal bone and the tendon (Spalteholz).

Relations.—By its superficial surface, with the deep fascia and the integument; by its deep surface, with the Flexor sublimis digitorum, Flexor longus pollicis, and wrist-joint; by its outer border, with the Pronator radii teres and the radial vessels; by its inner border, with the Palmaris longus above and the median nerve below.
The Palmaris Longus (Fig. 318) is a slender, fusiform muscle lying on the inner side of the preceding. It arises from the inner condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender flattened tendon, which passes over the upper part of the annular ligament, to end in the central part of the palmar fascia and lower part of the annular ligament, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent, and is subject to very considerable variations; it may be tendinous above and muscular below; or it may be muscular in the centre, with a tendon above and below; or it may present two muscular bundles with a central tendon; or finally it may consist simply of a mere tendinous band.

Relations.—By its superficial surface, with the deep fascia. By its deep surface, with the Flexor sublimis digitorum. Internally, with the Flexor carpi ulnaris. Externally, with the Flexor carpi radialis. The median nerve lies close to the tendon, just above the wrist, on its inner and posterior side.

The Flexor Carpi Ulnaris (Fig. 318) lies along the ulnar side of the forearm. It arises by two heads, connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head arises from the inner condyle of the humerus, humeral head (caput humerale), by the common tendon; the other from the inner margin of the olecranon and from the upper two-thirds of the posterior border of the ulna, ulnar head (caput ulnare), by an aponeurosis, common to it and the Extensor carpi ulnaris and Flexor profundus digitorum; and from the intermuscular septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon which occupies the anterior part of the lower half of the muscle, and is inserted into the pisiform bone, and is prolonged from this to the fifth metacarpal and unciform bones, by the piso-metacarpal and piso-uncinate ligaments: it is also attached by a few fibres to the annular ligament. The ulnar artery lies on the outer side of the tendon of this muscle, in the lower two-thirds of the forearm, the tendon forming a guide in tying the vessel in this situation. A bursa (bursa m. flexoris carpi ulnaris) is placed between the tendon and a part of the pisiform bone.

Relations.—By its superficial surface, with the deep fascia, with which it is intimately connected for a considerable extent; by its deep surface, with the Flexor sublimis digitorum, the Flexor profundus digitorum, the Pronator quadratus, and the ulnar vessels and nerve; by its outer or radial border, with the Palmaris longus above and the ulnar vessels and nerve below.
The Flexor Sublimis Digitorum (m. flexor digitorum sublimis) (Fig. 318) is placed beneath the preceding muscles, which therefore must be removed in order to bring its attachment into view. It is the largest of the muscles of the superficial layer, and arises by three heads. One head, the humeral head (caput humerale), arises from the internal condyle of the humerus by the common tendon, from the internal lateral ligament of the elbow-joint, and from the intermuscular septum common to it and the preceding muscles. The second head, ulnar head (caput ulnare), arises from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator radii teres (Fig. 133, p. 185). The third head, radial head (caput radiale), arises from the oblique line of the radius, extending from the tubercle to the insertion of the Pronator radii teres. The fibres pass vertically downward, forming a broad and thick muscle, which speedily divides into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane also divides into two parts, which end in tendons for the index and little fingers, but previously to having done so it gives off a muscular slip, which joins that part of the superficial plane which is intended for the ring finger. As the four tendons thus formed pass beneath the annular ligament into the palm of the hand, they are arranged in pairs, the superficial pair corresponding to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another as they pass onward. Opposite the bases of the first phalanges each tendon divides into two slips (chiasma tendinum) to allow of the passage of the corresponding tendon of the Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep flexor tendon. Finally they subdivide a second time, to be inserted into the sides of the second phalanges about their middle. The insertion in the index finger is shown in Fig. 324. After leaving the palm the tendons of the superficial flexor, accompanied by the deep flexor tendons, lie in osseo-aponeurotic canals (Fig. 320). Each canal or theca extends from the metacarpo-phalangeal articulation to the proximal end of the distal phalanx (Fig. 231). It is formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. It is very thin over the metacarpo-phalangeal articulation. It is absent over the distal phalanx. Each sheath is lined by a synovial membrane, which is reflected on the contained tendons.

Relations.—In the forearm, by its superficial surface, with the deep fascia and all the preceding superficial muscles; by its deep surface, with the Flexor profundus digitorum, Flexor longus pollicis, the ulnar vessels and nerve, and the median nerve. In the hand its tendons are in relation, in front, with the palmar fascia, superficial palmar arch, and the branches of the median nerve; behind, with the tendons of the deep Flexor and the Lumbricales.
The Deep Layer (Fig. 320).

Flexor profundus digitorum. Flexor longus pollicis. Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed.

The Flexor Profundus Digitorum (m. flexor digitorum profundus) (Fig. 320) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It arises from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and extending, below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an anepneosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons: these pass under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges the tendons pass through the openings in the two slips of the tendons of the Flexor sublimis digitorum, and are finally inserted into the bases of the last phalanges. The portion of the muscle for the index finger (Fig. 324) is usually distinct throughout, but the tendons for the three inner fingers are connected together by cellular tissue and tendinous slips as far as the palm of the hand. The tendons of this muscle and those of the Flexor sublimis digitorum, whilst contained in the osseo-aponeurotic canals of the fingers, are invested in a synovial sheath, and are connected to each other and to the phalanges by slender tendinous filaments, called vincula accessoria tendinum (vinctulum tendinum). One of these connects the deep tendon to the bone before it passes through the superficial tendon; a second connects the two tendons together, after the deep tendons have passed through; and a third connects the deep tendon to the head of the second phalanx. This last consists largely of yellow elastic tissue, and may assist in drawing down the tendon after flexion of the finger.¹

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles in that region.

Relations.—By its superficial surface, in the forearm, with the Flexor sublimis digitorum, the Flexor carpi ulnaris, the ulnar vessels and nerve, and the median nerve; and in the hand, with the tendons of the superficial Flexor; by its deep surface, in the forearm, with the ulna, the interosseous membrane, the Pronator quadratus; and in the hand, with the Interossei, Adductor pollicis, and deep palmar arch; by its ulnar border, with the Flexor carpi ulnaris; by its radial border, with the Flexor longus pollicis, the anterior interosseous vessels and nerve being interposed.

The Flexor Longus Pollicis (m. flexor pollicis longus) (Fig. 320) is situated on the radial side of the forearm, lying on the same plane as the preceding. It arises from the grooved anterior surface of the shaft of the radius, commencing above, immediately below the tuberosity and oblique line, and extending below to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane and generally by a fleshy slip from the inner border of the coronoid process or from the internal condyle of the humerus. The fibres pass downward, and terminate in a flattened tendon which passes beneath the annular ligament, is then lodged in the interspace between the outer head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and, entering an osseo-aponeurotic canal similar to those for the other flexor tendons, is inserted into the base of the last phalanx of the thumb.

Relations.—By its superficial surface, with the Flexor sublimis digitorum, Flexor carpi radialis, Supinator longus, and radial vessels; by its deep surface, with the radius, interosseous membrane, and Pronator quadratus; by its ulnar border, with the Flexor profundus digitorum, from which it is separated by the anterior interosseous vessels and nerve.

The Pronator Quadratus (Figs. 320 and 329) is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It arises from the oblique or pronator ridge on the lower part of the anterior surface of the shaft of the ulna; from the lower fourth of the anterior surface and the anterior border of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass outward and slightly downward, to be inserted into the lower fourth of the anterior surface and anterior border of the shaft of the radius.

Relations.—By its superficial surface, with the Flexor profundus digitorum, the Flexor longus pollicis, Flexor carpi radialis, and the radial vessels; by its deep surface, with the radius, ulna, and interosseous membrane.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar nerve. The Pronator radii teres and the Flexor carpi radialis derive their supply primarily from the sixth cervical; the Palmaris longus from the eighth cervical; the Flexor sublimis digitorum from the seventh and eighth cervical and first dorsal, and the Flexor carpi ulnaris from the eighth cervical and first dorsal nerves. Of the deep layer, the Flexor profundus digitorum is supplied by the eighth cervical and first dorsal through the ulnar and anterior interosseous branch of the median. The remaining two muscles, the

![Fig. 320.—Front of the left forearm. Deep muscles.](image-url)
Flexor longus pollicis and Pronator quadratus, are also supplied by the eighth cervical and first dorsal through the anterior interosseous branch of the median.

**Actions.**—These muscles act upon the forearm, the wrist, and hand. The Pronator radii teres helps to rotate the radius upon the ulna, rendering the hand prone: when the radius is fixed it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the flexors of the wrist; when acting alone it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, in bending the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist: when acting alone it flexes the wrist, inclining it to the ulnar side (adducts the wrist), and, by continuing to contract, it bends the elbow. The Palmaris longus is a tensor of the palmar fascia, and tension of this fascia protects the parts beneath it. It also assists in flexing the wrist and elbow. The Flexor sublimis digitorum flexes the middle phalanx and then assists in flexing the wrist and elbow. The Flexor profundus digitorum is the flexor of the distal phalanx. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one, but it cannot do so until after the contraction of the superficial muscle. After flexing the distal phalanx, it assists in flexing the middle phalanx, the proximal phalanx, and the wrist. The Flexor longus pollicis is the flexor of the distal phalanx of the thumb. When the thumb is fixed it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

**Surgical Anatomy.**—When a finger is amputated so that the fibrous sheath of the flexor tendons is divided in a region where it is firm and dense, the tendon contracts but the theca does not, and the rigid theca constitutes a permeable passage to the palm. If the parts should be infected the theca will draw pus toward the palm. Hence it is best to close the theca by sutures.

"Over the terminal phalanx, and over the joint between the middle and terminal phalanges, there is no fibrous sheath. In front of the metacarpo-phalangeal joint it is scarcely evident. Over the first and second (proximal and middle) phalanges, and in front of the joint between these bones, the fibrous sheath is well marked, and appears as a rigid tube when cut across. As the sheath crosses the metacarpo-phalangeal and first interphalangeal joints, it is adherent to the glenoid ligament, and is easily closed by two fine catgut sutures passed vertically—*i. e.*, from the dorsal to the palmar wall. Opposite the shafts of the first and second phalanges, however, there is much difficulty in effecting closure, since the sheath is united to the periosteum, and that membrane is very thin. In these situations the periosteum should be stripped up a little from the palmar aspect of the bone, and the orifice of the tube secured by two fine sutures passed either vertically or transversely, as may appear the more convenient. This stripping off of periosteum should be effected before the bone is divided."  

9. **The Radial Region** (Figs. 318, 321, 322).

*Supinator longus.*

*Extensor carpi radialis longior.*

**Dissection.**—Divide the integument in the same manner as in the dissection of the anterior brachial region, and, after having examined the cutaneous vessels and nerves and deep fascia, remove all those structures. The muscles will then be exposed. The removal of the fascia will be considerably facilitated by detaching it from below upward. Great care should be taken to avoid cutting across the tendons of the muscles of the thumb, which cross obliquely the larger tendons running down the back of the radius.

The **Supinator Longus** (*m. brachioradialis*) (Fig. 318) is the most superficial muscle on the radial side of the forearm; it is fleshy for the upper two-thirds of its extent, tendinous below. It *arises* from the upper two-thirds of the external supracondylar ridge of the humerus, and from the external intermuscular septum, being limited above by the musculo-spiral groove. The fibres terminate above the middle of the forearm in a flat tendon, which is inserted into the outer side of the base of the styloid process of the radius.

---

1 Operative Surgery. By Sir Frederick Treves.
Relations.—By its superficial surface, with the integument and fascia for the greater part of its extent; near its insertion it is crossed by the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis; by its deep surface, with the humerus, the Extensor carpi radialis longior and brevior, the insertion of the Pronator radii teres, and the Supinator brevis; by its inner border, above the elbow, with the Brachialis ancius, the musculo-spiral nerve, and the radial recurrent artery; and in the forearm with the radial vessels and nerve.

The **Extensor Carpi Radialis Longior** (*m. extensor carpi radialis longus*) (Fig. 321) is placed partly beneath the preceding muscle. It *arises* from the lower third of the external supracondylar ridge of the humerus, and from the external intermuscular septum by a few fibres from the common tendon of origin of the Extensor muscles of the forearm. The fibres terminate at the upper third of the forearm in a flat tendon, which runs along the outer border of the radius, beneath the extensor tendons of the thumb; it then passes through a groove common to it and the Extensor carpi radialis brevior, immediately behind the styloid process, and is *inserted* into the base of the metacarpal bone of the index finger, on its radial side.

Relations.—By its superficial surface, with the Supinator longus and fascia of the forearm; its outer side is crossed obliquely by the extensor tendons of the thumb; by its deep surface, with the elbow-joint, the Extensor carpi radialis brevior, and back part of the wrist.

The **Extensor Carpi Radialis Brevior** (*m. extensor carpi radialis brevis*) (Fig. 321) is shorter, as its name implies, and thicker than the preceding muscle, beneath which it is placed. It *arises* from the external condyle of the humerus by a tendon common to it and the three following muscles; from the external lateral ligament of the elbow-joint, from a strong aponeurosis which covers its
surface, and from the intermuscular septa between it and the adjacent muscles. The fibres terminate about the middle of the forearm in a flat tendon which is closely connected with that of the preceding muscle, and accompanies it to the wrist, lying in the same groove on the posterior surface of the radius; it passes beneath the extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is inserted into the base of the metacarpal bone of the middle finger, on its radial side. There is often a bursa (bursa m. extensoris carpi radialis brevis) between a portion of the base of the bone and the tendon.

The tendons of the two preceding muscles pass through the same compartment of the annular ligament, and are lubricated by a single synovial membrane, but are separated from each other by a small vertical ridge of bone as they lie in the groove at the back of the radius.

Relations.—By its superficial surface, with the Extensor carpi radialis longior, and with the Extensor muscles of the thumb which cross it; by its deep surface, with the Supinator brevis, tendon of the Pronator radii teres, radius, and wrist-joint; by its ulnar border, with the Extensor communis digitorum.

10. The Posterior Radio-ulnar Region (Fig. 321).

The muscles in this region are divided for purposes of description into two groups or layers, superficial and deep.

The Superficial Layer.

Extensor communis digitorum. Extensor carpi ulnaris.
Extensor minimi digiti. Anconeus.

The Extensor Communis Digitorum (m. extensor digitorum communis) is situated at the back part of the forearm. It arises from the external condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. Just below the middle of the forearm it divides into three fleshy masses, from which tendons proceed; these pass, together with the Extensor indicis, through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, the innermost one dividing into two; and all, after passing across the back of the hand, are inserted into the second and third phalanges of the fingers in the following manner: the outermost tendon, accompanied by the Extensor indicis, goes to the index finger (Figs. 321, 323, and 324); the second tendon is sometimes connected to the first by a thin transverse band, and receives a slip from the third tendon (Fig. 321); it goes to the middle finger; the third tendon gives off the slip to the second (Fig. 321), and receives a very considerable part of the fourth tendon; the fourth, or innermost tendon, divides into two parts: one goes to join the third tendon; the other, reinforced by the Extensor minimi digitii, goes to the little finger. Each tendon opposite the metacarpo-phalangeal articulation becomes narrow and thickened, and gives off a thin fasciculus upon each side of the joint, which blends with the lateral ligaments and serves as the posterior ligament; after having passed the joint it spreads out into a broad aponeurosis, which covers the whole of the dorsal surface of the first phalanx, being reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first phalangeal joint this aponeurosis divides into three slips, a middle and two lateral: the former is inserted into the base of the second phalanx; and the two lateral, which are continued onward along the sides of the second phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the last phalanx. As the tendons cross the phalangeal joints they furnish them with posterior ligaments. The accessory slips or lateral vincula which join the tendon
of the ring finger to the tendon of the little finger and the tendon of the middle finger are constant. If the middle and little fingers are held flexed the lateral vinculi greatly limit the range of extension possible in the ring finger—a limitation which interferes with a piano-player (Prof. William S. Forbes).

**Relations.**—By its *superficial surface*, with the fascia of the forearm and hand, the posterior annular ligament, and integument; by its *deep surface*, with the Supinator brevis, the Extensor muscles of the thumb and index finger, the posterior interosseous vessels and nerve, the wrist-joint, carpus, metacarpus, and phalanges; by its *radial border*, with the Extensor carpi radialis brevior; by its *ulnar border*, with the Extensor minimi digiti and Extensor carpi ulnaris.

The **Extensor Minimi Digiti** (*m. extensor digiti quinti proprius*) is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It *arises* from the common tendon by a thin, tendinous slip, and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate compartment in the annular ligament behind the inferior radio-ulnar joint, then divides into two as it crosses the hand, the outermost division being joined by the slip from the innermost tendon of the common extensor. The two slips thus formed spread into a broad aponeurosis, which after receiving a slip from the Abductor minimi digiti is *inserted* into the second and third phalanges. The tendon is situated on the ulnar side of, and somewhat more superficial than, the common extensor.

The **Extensor Carpi Ulnaris** is the most superficial muscle on the ulnar side of the forearm. It *arises* from the external condyle of the humerus by the common tendon; by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon which runs through a groove behind the styloid process of the ulna, passes through a separate compartment in the annular ligament, and is *inserted* into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

**Relations.**—By its *superficial surface*, with the deep fascia of the forearm; by its *deep surface*, with the ulna and the muscles of the deep layer.

The **Anconeus** (*m. anconaeus*) is a small triangular muscle placed behind and below the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It *arises* by a separate tendon from the back part of the outer condyle of the humerus, and is *inserted* into the side of the olecranon and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inward.

*Relations.*—By its *superficial surface*, with a strong fascia derived from the Triceps; by its *deep surface*, with the elbow-joint, the orbicular ligament, the ulna, and a small portion of the Supinator brevis.

**The Deep Layer** (Fig. 323).

- Supinator radii brevis
- Extensor ossis metacarpi pollicis
- Extensor brevis pollicis
- Extensor longus pollicis
- Extensor indicis

The **Supinator Radii Brevis** (*m. supinator*) (Figs. 322 and 323) is a broad muscle, of hollow cylindrical form, curved round the upper third of the radius. It consists of two distinct planes of muscular fibres, between which lies the posterior interosseous nerve (Fig. 322). The two planes *arise* in common: the superficial one by tendinous, and the deeper by muscular, fibres from the external condyle of the humerus; from the external lateral ligament of the elbow-joint and the orbicular ligament of the radius; from the ridge on the ulna, which runs obliquely downward from the
posterior extremity of the lesser sigmoid cavity; from the triangular depression in front of it; and from a tendinous expansion which covers the surface of the muscle.

The superficial fibres surround the upper part of the radius, and are inserted into the outer edge of the bicipital tuberosity and into the oblique line of the radius, as low down as the insertion of the Pronator radii teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its inner surface; the greater part of this portion of the muscle is inserted into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone. Between the insertion of the two planes the posterior interosseous nerve lies on the shaft of the bone (Fig. 322).
Relations.—By its superficial surface, with the superficial Extensor and Supinato r muscles, and the radial vessels and nerve; by its deep surface, with the elbow joint, the interosseous membrane, and the radius.

The Extensor Ossis Metacarpi Pollicis (m. abductor pollicis longus) is the most external and the largest of the deep extensor muscles; it lies immediately below the Supinator brevis, with which it is sometimes united. It arises from the outer part of the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the shaft of the radius. Passing obliquely downward and outward, it terminates in a tendon which runs through a groove on the outer side of the styloid process of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is inserted into the base of the metacarpal bone of the thumb. It occasionally gives off two slips near its insertion—one to the Trapeziun, and the other to blend with the origin of the Abductor pollicis.

Relations.—By its superficial surface, with the Extensor communis digitorum, Extensor minimi digiti, and fascia of the forearm, and with the branches of the posterior interosseous artery and nerve which cross it; by its deep surface, with the ulna, interosseous membrane, radius, the tendons of the Extensor carpi radialis longior and brevior, which it crosses obliquely, and, at the outer side of the wrist, with the radial vessels; by its upper border, with the Supinator brevis; by its lower border, with the Extensor brevis pollicis.

The Extensor Brevis Pollicis, often called the extensor primi internodii pollicis (m. extensor pollicis brevis), the smallest muscle of this group, lies on the inner side of the preceding. It arises from the posterior surface of the shaft of the radius, below the Extensor ossis metacarpi pollicis, and from the interosseous membrane. Its direction is similar to that of the Extensor ossis metacarpi pollicis, its tendon passing through the same groove on the outer side of the styloid process, to be inserted into the base of the first phalanx of the thumb.

Relations.—The same as those of the Extensor ossis metacarpi pollicis.

The Extensor Longus Pollicis, often called the extensor secundi internodii pollicis (m. extensor pollicis longus) is much larger than the preceding muscle, the origin of which it partly covers in. It arises from the outer part of the posterior surface of the shaft of the ulna, below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon which passes through a separate compartment in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and brevior, being separated from the other extensor tendons of the thumb by a triangular interval, in which the radial artery is found, and is finally inserted into the base of the last phalanx of the thumb.

Relations.—By its superficial surface, with the same parts as the Extensor ossis metacarpi pollicis; by its deep surface, with the ulna, interosseous membrane, the
posterior interosseous nerve, radius, the wrist, the radial vessels, and metacarpal bone of the thumb.

The **Extensor Indicis** (*m. extensor indicis proprius*) (Figs. 321, 323, and 324) is a narrow, elongated muscle placed on the inner side of, and parallel with, the preceding. It *arises* from the posterior surface of the shaft of the ulna, below the origin of the Extensor longus pollicis and from the interosseous membrane. Its tendon passes with the Extensor communis digitorum through the same canal in the annular ligament, and subsequently joins the tendon of the Extensor communis which belongs to the index finger, opposite the lower end of the corresponding metacarpal bone, lying to the ulnar side of the tendon from the common extensor.

**Relations.**—The relations are similar to those of the preceding muscles.

**Nerves.**—The Supinator longus is supplied by the sixth, the Extensor carpi radialis longior by the sixth and seventh, and the Anconeus by the seventh and eighth cervical nerves, all through the musculo-spiral nerve; the remaining muscles of the radial and posterior brachial region are supplied through the posterior interosseous nerve, the Supinator brevis being supplied by the sixth cervical, the Extensor carpi radialis brevior by the sixth and seventh cervical, and all the other muscles by the seventh cervical.

**Actions.**—The muscles of the radial and posterior brachial regions, which comprise all the extensor and supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the pronator and flexor muscles. The Anconeus assists the Triceps in extending the forearm. The chief action of the Supinator longus is that of a flexor of the elbow-joint, but in addition to this it may act both as a supinator or a pronator; that is to say, if the forearm is forcibly pronated it will act as a supinator, and bring the bones into a position midway between supination and pronation; and *vice versa*, if the arm is forcibly supinated, it will act as a pronator, and bring the bones into the same position, midway between supination and pronation. The action of the muscle is therefore to throw the forearm and hand into the position they naturally occupy when placed across the chest. The Supinator brevis is a supinator; that is to say, when the radius has been carried across the ulna in pronation and the back of the hand is directed forward, this muscle carries the radius back again to its normal position on the outer side of the ulna, and the palm of the hand is again directed forward. The Extensor carpi radialis longior extends the wrist and abducts the hand. It may also assist in bending the elbow-joint; at all events, it serves to fix or steady this articulation. The Extensor carpi radialis brevior assists the Extensor carpi radialis longior in extending the wrist, and may also act slightly as an adductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it toward the ulnar side; by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the middle and terminal phalanges being extended by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends similarly the little finger, and by its continued action it assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed whilst the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outward and backward from the palm of the hand, and hence it has been called the **abductor pollicis longus**. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the index finger, and
by its continued action assists in extending the wrist. It is owing to this muscle that the index finger can be extended or pointed while the others are flexed.

**Surgical Anatomy.**—The tendons of the extensor muscles of the thumb are liable to become strained and their sheaths inflamed after excessive exercise, producing a sausage-shaped swelling along the course of the tendon, and giving a peculiar creaking sensation to the finger when the muscle acts. In consequence of its often being caused by such movements as wringing clothes, it is known as washerwoman’s sprain. In piano-players the slips which join the tendons of the Extensor communis digitorum may limit freedom of motion in individual fingers. "When the middle finger and little finger of the hand are brought down by the flexor muscles, and their balls are held down firmly against the keys of a musical instrument, as in performing on a piano for the purpose of producing continuous sounds, and when at the same time it is necessary to extend and then to flex the ring-finger in order to produce accompanying sounds, it will be found that in the still-flexed position of the middle and little fingers, the ring finger can be but very slightly extended. Its complete extension, without operative interference, can only be brought about by long-continued exertion in practice, when elongation of certain accessory, but restricting, tendons is made by nutritive growth." 1 If there is much limitation division of the hindering slips is proper. This was suggested by Prof. William S. Forbes in 1857.

**IV. MUSCLES AND FASCIAE OF THE HAND.**

The muscles of the hand are subdivided into three groups: 1. Those of the thumb, which occupy the radial side and produce the *thenar eminence*. 2. Those of the little finger, which occupy the ulnar side and give rise to the *hypothenar eminence*. 3. Those in the middle of the palm and within the interosseous spaces.

**Dissection** (Fig. 312).—Make a transverse incision across the front of the wrist, and a second across the heads of the metacarpal bones: connect the two by a vertical incision in the middle line, and continue it through the centre of the middle finger. The anterior and posterior annular ligaments and the palmar fascia should then be dissected.

The *Ligamentum Carpi Volare* is a thickening of the deep fascia of the forearm (*fascia antibrachii*) by deep fibres just above the wrist (Fig. 330). It covers the flexor muscles and joins the anterior annular ligament.

The *Anterior Annular Ligament* (*ligamentum carpi transversum*) (Fig. 325) is a strong, fibrous band which arches over the carpus, converting the deep groove on the front of the carpal bones into a canal, beneath which pass the flexor tendons of the fingers. It is attached, internally, to the pisiform bone and

---

the hook of the unciform bone \((\text{eminentia carpi ulnaris})\), and externally to the tuberosity of the scaphoid and to the inner part of the anterior surface and the ridge of the trapezium \((\text{eminentia carpi radialis})\). It is continuous, above, with the deep fascia of the forearm, of which it may be regarded as a thickened portion, and, below, with the palmar fascia. It is crossed by the ulnar vessels and nerve and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligaments to the bone. It has inserted into its anterior surface a part of the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from it, below, the small muscles of the thumb and little finger. Beneath it pass the tendons of the Flexor sublimis and Profundus digitorum, the Flexor longus pollicis, and the median nerve.

**The Synovial Membranes of the Flexor Tendons at the Wrist.**—There are two vaginal synovial membranes which enclose all the tendons as they pass beneath this ligament—one for the Flexor sublimis and Profundus digitorum, the other for the Flexor longus pollicis. They extend up into the forearm for about an inch above the annular ligament, and downward about half-way along the metacarpal bone, where they terminate in a blind diverticulum around each pair of tendons, with the exception of that of the thumb and those of the little finger—in each of these two digits the diverticulum is continued on, and communicates with the synovial sheath of the tendons in the fingers. In the other three fingers the synovial sheath of the tendons begins as a blind pouch without communication with the large synovial sac (Fig. 326).

**Surgical Anatomy.**—This arrangement of the synovial sheaths explains the fact that thecal abscess in the thumb and little finger is liable to be followed by abscesses in the forearm, from extension of the inflammation along the continuous synovial sheaths. Tuberculous inflammation is apt to occur in this situation, constituting \textit{compound palmar ganglion}; it presents an hour-glass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction corresponding to the annular ligament between the two. The fluid can be forced from the one swelling to the other under the ligament.

**Bursæ about the Hand and Wrist.**—Bursæ usually exist between the distal extremities of the metacarpal bones \((\text{bursæ intermetacarpophalangea})\), and a subcutaneous bursa often exists over the dorsal surface of the head of the fifth metacarpal bone. Subcutaneous digital dorsal bursæ occur “almost constantly in the first finger-joints (between the first and second phalanx), occasionally in the second joint of the second and fourth fingers”\(^1\). \((\text{bursæ subcutanea digitorum dorsales})\). A bursa exists between the tendon of the Extensor carpi radialis brevior and the base of the third metacarpal bone; another between the Flexor carpi ulnaris and the pisiform bone; another between the Flexor carpi radialis and the base of the second metacarpal bone.

---

The Posterior Annular Ligament (ligamentum carpi dorsale) is a strong fibrous band extending obliquely downward and inward across the back of the wrist, and consisting of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It binds down the extensor tendons in their passage to the fingers, being attached, internally, to the styloid process of the ulna, the cuneiform and pisiform bones; externally, to the margin of the radius; and, in its passage across the wrist, to the elevated ridges on the posterior surface of the radius. It presents six compartments for the passage of tendons, each of which is lined by a separate synovial membrane (Fig. 327). These are, from without inward: 1. On the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis. 2. Behind the styloid process, for the tendons of the Extensor carpi radialis longior and brevier. 3. About the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis. 4. To the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis. 5. Opposite the interval between the radius and ulna, for the Extensor minimi digitii. 6. Grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris. The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament down upon the tendons for a variable distance on the back of the hand.

The Deep Palmar Fascia (aponeurosis palmaris).—The deep palmar fascia (Fig. 328) forms a common sheath which invests the muscles of the hand. It consists of a central and two lateral portions.

The Central Portion occupies the middle of the palm, is triangular in shape, of great strength and thickness, and binds down the tendons and protects the vessels and nerves in this situation. It is narrow above, where it is attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. Below, it is broad and expanded, and divides into four slips for the four fingers. Each slip gives off superficial fibres, which are inserted into the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpo-phalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the lateral margins of the anterior (glenoid) ligament of the metacarpo-phalangeal joint. From the sides of these processes offsets are sent backward, to be attached to the borders of the lateral surfaces of the metacarpal bones at their distal extremities. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the flexor tendons pass. Dr. W. W. Keen describes a fifth slip as frequently found passing to the thumb. The intervals left in the fascia between the four fibrous slips transmit the digital vessels and nerves and the tendons of the Lumbricales. At the points of division of the palmar fascia into the slips above mentioned numerous strong, transverse fibres bind the separate processes together. The palmar fascia is intimately adherent to the integument by dense fibro-areolar tissue, forming the superficial palmar fascia, and gives origin by its inner margin to the Palmaris brevis: it covers the superficial palmar arch, the tendons of the flexor muscles, and the branches of
the median and ulnar nerves, and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis and separates the lateral from the middle palmar group of muscles.

The **Lateral Portions of the Palmar Fascia** are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger; they are continuous with the dorsal fascia, and in the palm with the central portion of the palmar fascia.

The **Superficial Transverse Ligament of the Fingers** is a thin, fibrous band which stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onward to their destination.

**Surgical Anatomy.**—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity known as **Dupuytren's contraction**. The ring and little fingers are most frequently implicated, but the middle, index, and the thumb may be involved. The proximal phalanx is drawn down and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.
11. The Radial Region (Figs. 329, 330).

Abductor pollicis. Flexor brevis pollicis.
Opponens pollicis. Adductor obliquus pollicis.
Adductor transversus pollicis.

The Abductor Pollicis (m. abductor pollicis brevis) (Fig. 330) is a thin, flat muscle, placed immediately beneath the integument. It arises from the anterior annular ligament, the tuberosity of the scaphoid, and the ridge of the trapezium, frequently by two distinct slips; and, passing outward and downward, is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb, sending a slip to join the tendon of the Extensor longus pollicis.

Fig. 329.—Adductor pollicis, Opponens pollicis, and Pronator quadratus. (Testut.)
Relations.—By its superficial surface, with the palmar fascia and superficialis volae artery, which frequently perforates it. By its deep surface, with the Opponens pollicis, from which it is separated by a thin aponeurosis. Its inner border is separated from the Flexor brevis pollicis by a narrow cellular interval.

The Opponens Pollicis (Figs. 329 and 330), often called the flexor ossis metacarpi pollicis, is a small, triangular muscle, placed beneath the preceding. It arises from the palmar surface of the ridge on the trapezium and from the annular ligament, passes downward and outward, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.
Relations.—By its superficial surface, with the Abductor and Flexor brevis pollicis. By its deep surface, with the trapezio-metacarpal articulation. By its inner border, with the Adductor obliquus pollicis.

The Flexor Brevis Pollicis (\textit{m. flexor pollicis brevis}) (Fig. 330) consists of two portions, outer and inner. The outer and more superficial portion arises from the outer two-thirds of the lower border of the anterior annular ligament, and passes along the outer side of the tendon of the Flexor longus pollicis; and, becoming tendinous, has a sesamoid bone developed in its tendon, and is inserted into the outer side of the base of the first phalanx of the thumb. The inner and deeper portion of the muscle is very small, and arises from the ulnar side of the first metacarpal bone beneath the Adductor obliquus pollicis, and is inserted into the inner side of the base of the first phalanx with this muscle.

Relations.—By its superficial surface, with the palmar fascia. By its deep surface, with the tendon of the Flexor longus pollicis. By its external surface, with the Opponens pollicis. Behind, with the Adductor obliquus pollicis.

The Adductor Obliquis Pollicis (\textit{m. adductor pollicis}) (Figs. 329 and 330) arises by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior carpal ligaments, and the sheath of the tendon of the Flexor carpi radialis. From this origin the greater number of fibres pass obliquely downward and converge to a tendon, which, uniting with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is inserted into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however, passes more obliquely outward beneath the tendon of the long flexor to join the superficial portion of the short flexor and the Adductor pollicis.¹

Relations.—By its superficial surface, with the Flexor longus pollicis and the outer head of the Flexor brevis pollicis. Its deep surface is in relation with the deep palmar arch, which passes between the two adductors.

The Adductor Transversus Pollicis (Figs. 329 and 330) is the most deeply seated of this group of muscles. It is of a triangular form, arising, by its broad base, from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface; the fibres, proceeding outward, converge to be inserted, with the inner part of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb. From the common tendon of insertion a slip is prolonged to the Extensor longus pollicis. The name \textit{adductor pollicis} is frequently used to mean both of the adductors (Figs. 329 and 330).

Relations.—By its superficial surface, with the Adductor obliquus pollicis, the tendons of the Flexor profundus, and the Lumbricales. Its deep surface covers the first two interosseous spaces, from which it is separated by a strong aponeurosis.

Three of these muscles of the thumb, the Abductor, the Adductor transversus, and the Flexor brevis pollicis, at their insertions give off fibrous expansions which join the tendon of the Extensor longus pollicis. This permits of flexion of the proximal phalanx and extension of the terminal phalanx at the same time. These expansions, originally figured by Albinus, have been more recently described by M. Duchenne.²

Nerves.—The Abductor, Opponens, and outer head of the Flexor brevis pollicis are supplied by the sixth cervical through the median nerve; the inner head of the Flexor brevis, and the Adductors, by the eighth cervical through the ulnar nerve.

¹ This muscle is described by some as the deep portion of the Flexor brevis pollicis.
² Physiologie des Mouvements.
Actions.—The actions of the muscles of the thumb are almost sufficiently indicated by their names. This segment of the hand is provided with three extensors—an extensor of the metacarpal bone, an extensor of the first, and an extensor of the second phalanx; these occupy the dorsal surface of the forearm and hand. There are also three flexors on the palmar surface—a flexor of the metacarpal bone, a flexor of the proximal, and a flexor of the terminal phalanx; there is also an Abductor and two Adductors. The Abductor pollicis moves the metacarpal bone of the thumb outward; that is, away from the index finger. The Flexor ossis metacarpi pollicis flexes the metacarpal bone—that is, draws it inward over the palm—and at the same time rotates the bone, so as to turn the ball of the thumb toward the fingers, thus producing the movement of opposition. The Flexor brevis pollicis flexes and addsucts the proximal phalanx of the thumb. The Adductores pollicis move the metacarpal bone of the thumb inward; that is, toward the index finger. These muscles give to the thumb its extensive range of motion. It will be noticed, however, that in consequence of the position of the first metacarpal bone, these movements differ from the corresponding movements of the metacarpal bones of the other fingers. Thus extension of the thumb more nearly corresponds to the motion of abduction in the other fingers, and flexion to adduction.

12. The Ulnar Region (Fig. 330).

The Palmaris Brevis is a thin quadrilateral muscle placed beneath the integument on the ulnar side of the hand. It arises by tendinous fasciculi from the anterior annular ligament and palmar fascia; the fleshy fibres pass inward, to be inserted into the skin on the inner border of the palm of the hand.

Relations.—By its superficial surface, with the integument, to which it is intimately adherent, especially by its inner extremity; by its deep surface, with the inner portion of the palmar fascia, which separates it from the ulnar vessels and nerve, and from the muscles of the ulnar side of the hand.

The Abductor Minimi Digitii (m. abductor digitii quinti) is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and terminates in a flat tendon, which divides into two slips; one is inserted into the ulnar side of the base of the first phalanx of the little finger. The other slip is inserted into the ulnar border of the aponeurosis of the Extensor minimi digitii.

Relations.—By its superficial surface, with the inner portion of the palmar fascia and the Palmaris brevis; by its deep surface, with the Opponens minimi digitii; by its outer border, with the Flexor brevis minimi digitii.

The Flexor Brevis Minimi Digitii (m. flexor digitii quinti brevis) lies on the same plane as the preceding muscle, on its radial side. It arises from the convex aspect of the hook of the unciform bone and anterior surface of the annular ligament, and is inserted into the inner side of the base of the first phalanx of the little finger. It is separated from the Abductor at its origin by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.

Relations.—By its superficial surface, with the internal portion of the palmar fascia and the Palmaris brevis; by its deep surface, with the Opponens. The deep branch of the ulnar artery and the corresponding branch of the ulnar nerve pass between the Abductor and Flexor brevis minimi digitii muscles.

The Opponens Minimi Digitii (m. opponens digitii quinti).—This muscle is sometimes called the flexor ossis metacarpi (Fig. 320), is of a triangular form, and placed immediately beneath the preceding muscles. It arises from the convexity
of the hook of the unciform bone and the contiguous portion of the anterior annular ligament; its fibres pass downward and inward, to be inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

**Relations.**—By its superficial surface, with the Flexor brevis and Abductor minimi digiti; by its deep surface, with the Interossei muscles in the fourth metacarpal space, the metacarpal bone, and the Flexor tendons of the little finger.

**Nerves.**—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

**Actions.**—The Abductor minimi digiti abducts the little finger from the middle line of the hand. It corresponds to a dorsal interosseous muscle. It also assists in flexing the proximal phalanx and extending the second and third phalanges. The Flexor brevis minimi digiti abducted the little finger from the middle line of the hand. It also assists in flexing the proximal phalanx. The Opponens minimi digiti draws forward the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the inner side of the palm of the hand and probably serves to protect the ulnar nerve and artery from damage by the pressure of grasping a hard object.

**THE MIDDLE PALMAR REGION**

13. **The Middle Palmar Region.**

**Lumbricales.**

**Interossei palmares.**

**Interossei dorsales.**

The **Lumbricales** (Fig. 330) are four small fleshy fasciculi, accessories to the deep Flexor muscle. They arise from the tendons of the deep Flexor: the first and second, from the radial side and palmar surface of the tendons of the index and middle fingers respectively; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. They pass to the radial side of the corresponding fingers and opposite the metacarpo-phalangeal articulation each tendon is inserted into the tendinous expansion of the Extensor communis digitorum, covering the dorsal aspect of each finger.

The **Interossei Muscles** (Figs. 331 and 332) are so named from occupying the intervals between the metacarpal bones, and are divided into two sets, dorsal and palmar.

The **Dorsal interossei** (mm. interossei dorsales) are four in number, larger than the palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeurosis of the common Extensor tendon. Between the double origin of each of these muscles is a narrow triangular interval, through the first of which passes the radial artery; through each of the other three passes a perforating branch from the deep palmar arch.

The **First dorsal interosseous muscle** or **Abductor indicis** is larger than the others. It is flat, triangular in form, and arises by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of the hand. The **outer head** arises from the upper half of the ulnar border of the first metacarpal bone; the **inner head**, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The **second and third dorsal interossei** are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The **fourth** is inserted into the ulnar side of the ring finger.

The **Palmar interossei** (mm. interossei volares), three in number, are smaller than the Dorsal, and placed upon the palmar surface of the metacarpal bones, rather
than between them. Each muscle arises from the entire length of the metacarpal bone of one finger, and is inserted into the side of the base of the first phalanx and aponeurotic expansion of the common extensor tendon of the same finger. The first arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The second arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The third arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with two Interosseous muscles, with the exception of the little finger, in which the Abductor muscle takes the place of one of the pair.

Nerves.—The two outer Lumbricales are supplied by the sixth cervical nerve, through the third and fourth digital branches of the median nerve: the two inner Lumbricales and all the Interossei are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. Brooks states that the third lumbrical received a twig from the median in twelve out of twenty-one cases.

Actions.—The Palmar interossei muscles adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the Dorsal interossei abduct the fingers from that line. In addition to this, the Interossei, in conjunction with the Lumbricales, flex the first phalanges at the metacarpo-phalangeal joints, and extend the second and third phalanges in consequence of their insertion into the expansion of the extensor tendons. The Extensor communis digitorum is believed to act almost entirely on the first phalanges.

SURFACE FORM OF THE UPPER EXTREMITY.

The Pectoralis major muscle largely influences surface form and conceals a considerable part of the thoracic wall in front. Its sternal origin presents a festooned border which bounds and determines the width of the sternal furrow. Its clavicular origin is somewhat depressed and flattened, and between the two portions of the muscle is often an oblique depression which differentiates the one from the other. The outer margin of the muscle is generally well marked above, and bounds the infraclavicular fossa, a triangular interval which separates the Pectoralis major
from the Deltoid. It gradually becomes less marked as it approaches the tendon of insertion, and becomes more closely blended with the Deltoid muscle. The lower border of the Pectoralis major forms the rounded anterior axillary fold, and corresponds with the direction of the fifth rib. The Pectoralis minor muscle influences surface form. When the arm is raised its lowest slip of origin produces a local fulness just below the border of the anterior fold of the axilla, and so serves to break the sharp line of the lower border of the Pectoralis major muscle, which is produced when the arm is in this position. The origin of the Serratus magnus muscle produces a very characteristic surface marking. When the arm is raised from the side in a well-developed subject, the five or six lower serrations are plainly discernible, forming a zigzag line, caused by the series of digitations, which diminish in size from above downward, and have their apices arranged in the form of a curve. When the arm is lying by the side, the first serration to appear, at the lower margin of the Pectoralis major, is the one attached to the fifth rib. The Deltoid muscle, with the prominence of the upper extremity of the humerus, produces the rounded outline of the shoulder. It is rounder and fuller in front than behind, where it presents a somewhat flattened form. Its anterior border, above, presents a rounded, slightly curved eminence, which bounds externally the infraclavicular fossa; below, it is closely united with the Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. When the muscle is in action, the middle portion becomes irregular, presenting alternate longitudinal elevations and depressions, the elevations corresponding to the fleshy portions, the depressions to the tendinous intersections of the muscle. The insertion of the Deltoid is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the Teres major, which assists the Latissimus dorsi in forming the thick, rounded fold of the posterior boundary of the axilla. When the arm is raised, the Coraco-brachialis reveals itself as a long, narrow elevation which emerges from under cover of the anterior fold of the axilla and runs downward, internal to the shaft of the humerus. When the arm is hanging by the side, its front and inner part presents the prominence of the Biceps, bounded on either side by an intermuscular depression. This muscle determines the contour of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper tendons are concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form, bulged out laterally, and its length is diminished. On each side of the Biceps, at the lower part of the arm, the Brachialis anticus is discernible. On the outer side it forms a narrow eminence which extends some distance up the arm along the border of the Biceps. On the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the Triceps may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the tendon of the muscle on the lower part of the back of the arm. The tendon of insertion of the muscle extends about halfway up the back of the arm, where it forms an elongated flattened plane when the muscle is in action. Under similar conditions the surface forms produced by the three heads of the muscle are well seen. On the anterior aspect of the elbow are to be seen two muscular elevations, one on each side, separated above and converging below so as to form a triangular space. Of these, the inner elevation, consisting of the flexors and pronator, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle and gradually tapering off below. The Pronator radii teres, the innermost muscle of the group, forms the boundary of the triangular space at the bend of the elbow. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the Flexor carpi radialis, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and can be traced downward to its tendon, which can be felt lying on the front of the wrist, nearer to the radial than to the ulnar border, and to the inner side of the radial artery. The Palmaris longus presents no surface marking above, but below is the most prominent tendon on the front of the wrist, standing out, when the muscle is in action, as a sharp, tense cord beneath the skin. The Flexor sublimis digitorum does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the Palmaris longus and the Flexor carpi ulnaris. The Flexor carpi ulnaris occupies a small part of the posterior surface of the forearm, and is separated from the extensor and supinator group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The deep muscles of the front of the forearm have no direct influence on surface form. The external group of muscles of the forearm, consisting of the extensors and supinators, occupy the outer and a considerable portion of the posterior surface of this region. It has a fusiform outline, which is altogether on a higher level than the pronato-flexor group. Its apex emerges from between the Triceps and Brachialis anticus muscles some distance above the
elbow-joint, and acquires its greatest breadth opposite the external condyle, and thence gradually shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these two groups of muscles consists of the Supinator longus and the Extensor carpi radialis longior et brevior, which form a longitudinal eminence descending from the external condylar ridge in the direction of the styloid process of the radius. The other and more posterior group consists of the Extensor communis digitorum, the Extensor minimi digiti, and the Extensor carpi ulnaris. It commences above as a tapering form at the external condyle of the humerus, and is separated behind at its upper part from the Anconeus by a well-marked furrow, and below, from the pronato-flexor mass, by the ulnar furrow. In the triangular interval left between these two groups the extensors of the thumb and index finger are seen. The only two muscles of this region which require special mention as independently influencing surface form are the Supinator longus and the Anconeus. The inner border of the Supinator longus forms the outer boundary of the triangular space at the bend of the elbow. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down, the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced down to the styloid process of the radius. The Anconeus presents a well-marked and characteristic surface form in the shape of a triangular, slightly elevated surface, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common extensor group by a well-marked oblique longitudinal depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the interval caused by the divergence from each other of the two groups of muscles into which the extensor and supinator group is divided at the lower part of the forearm an oblique elongated eminence is seen, caused by the emergence of two of the extensors of the thumb from their deep origin at the back of the forearm. This eminence, full above and becoming flattened out and partially subdivided below, runs downward and outward over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, which passes onward to the posterior aspect of the thumb. The tendons of most of the extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are the tendons of the Extensor ossis metacarpii pollicis and the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint from the styloid process of the radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevior can be distinctly perceived as a vertical ridge emerging from under the inner border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this, again, can be felt the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digitii; the latter tendon being separated from those of the common extensor by a slight furrow. The muscles of the hand are principally concerned, as far as regards surface-form, in producing the thenar and hypothenar eminences, and individually are not to be distinguished, on the surface, from each other. The Adductor transversus pollicis is, however, an exception to this; its anterior border gives rise to a ridge across the web of skin connecting the thumb to the rest of the hand. The thenar eminence is much larger and rounder than the hypothenar one, which presents a longer and narrower eminence along the ulnar side of the hand. When the Palmaris brevis is in action it produces a wrinkling of the skin over the hypothenar eminence, and a deep dimple on the ulnar border of the hand. The anterior extremities of the Lumbrical muscles help to produce the soft eminences just behind the clefts of the fingers, separated from each other by depressions corresponding to the flexor tendons in their sheaths. Between the thenar and hypothenar eminences, at the wrist-joint, is a slight groove or depression, widening out as it approaches the fingers; beneath this we have the strong central part of the palmar fascia. Here we have some furrows, which are pretty constant in their arrangement, and bear some resemblance to the letter M. One of these furrows passes obliquely outward from the groove between the thenar and hypothenar regions near the wrist to the head of the metacarpal bone of the index finger. A second passes inward, with a slight inclination upward, from the termination of the first to the ulnar side of the hand. A third runs nearly parallel with the second and about three-quarters of an inch below it. Lastly, crossing these two latter furrows, is an oblique furrow parallel with the first. The skin of the palm of the hand differs considerably from that of the forearm. At the wrist it suddenly becomes hard and dense, and covered with a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density, the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and no sebaceous follicles have been found in this region. Over the fingers the skin again becomes thinner, especially at the flexures of the joints, and over the terminal phalanges it is thrown into numerous ridges in consequence of the arrangement of the papillae in it. These ridges form, in different individuals, distinctive and permanent patterns, which may be used for purposes of identification. The superficial fascia in the palm
is made up of dense fibro-fatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two. On the back of the hand the Dorsal interossei produce elongated swellings between the metacarpal bones. The first dorsal interosseous (Abductor indicis), when the thumb is closely adducted to the hand, forms a prominent fusiform bulging; the other interossei are not so marked.

SURGICAL ANATOMY OF THE UPPER EXTREMITY.

The student, having completed the dissection of the muscles of the upper extremity, should consider the effects likely to be produced by the action of the various muscles in fracture of the bones.

In considering the actions of the various muscles upon fractures of the upper extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the middle of the clavicle (Fig. 333) is always attended with considerable displacement; the inner end of the outer fragment is displaced inward and backward, while the outer end of the same fragment is rotated forward. The whole outer fragment is somewhat depressed. The deformity is described by saying that the shoulder goes downward, forward, and inward.

The displacement is produced as follows: inward, by the muscles passing from the chest to the outer fragment of the clavicle, to the scapula, and to the humerus—viz., the Subclavius and the Pectoralis minor, and, to a less extent, the Pectoralis major and the Lattissimus dorsi; backward, in consequence of the rotation of the outer fragment. The Serratus magnus causes the scapula to rotate on the wall of the chest; this carries the acromion and outer end of the outer fragment of the clavicle forward and causes the piece of bone to rotate round a vertical axis through its centre, and so carries the inner end of the outer portion backward. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The outer end of the inner fragment appears to be elevated, the skin being drawn tensely over it; this is owing to the depression of the outer fragment, as the inner fragment is usually kept fixed by the costo-clavicular ligament and by the antagonism between the Sternomastoid and Pectoralis major muscles. But it may be raised by an unusually strong Sterno-mastoid, or by the inner end of the outer fragment getting below and behind it. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outward, and, together with the scapula, raised upward to a level with the inner fragment, and retained in that position. The formula for correcting the deformity is as follows: carry the shoulder upward, outward, and backward.

In fracture of the acromial end of the clavicle, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the sternal end, internal to the costo-clavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the acromion process usually arises from violence applied to the upper and outer part of the shoulder; it is generally known by the rotundity of the shoulder being lost, from the Deltoid drawing the fractured portion downward and forward; and the displacement may easily be discovered by tracing the margin of the clavicle outward, when the fragment will be found resting on the front and upper part of the head of the humerus. In order to relax the anterior and outer fibres of the Deltoid (the opposing muscle), the arm should be drawn forward across the chest and the elbow well raised, so that the head of the bone may press the acromion process upward and retain it in its position.

Fracture of the coracoid process is an extremely rare accident, and is usually caused by a sharp blow on the point of the shoulder. Displacement is here produced by the combined actions of the Pectoralis minor, short head of the Biceps, and Coraco-brachialis, the former muscle drawing the fragment inward, and the latter muscles directly downward, the amount of displacement being limited by the connection of this process to the acromion by means of the coraco-acromial ligament. In many cases there appears to have been little or no displacement,
from the fact that the coraco-clavicular ligament has remained intact, and has kept the separated fragment from displacement. In order to relax these muscles and replace the fragments in close apposition, the forearm should be flexed so as to relax the Biceps, and the arm drawn forward and inward across the chest, so as to relax the Coraco-brachialis; the humerus should then be pushed upward against the coraco-acromial ligament, and the arm retained in that position.

Fracture of the surgical neck of the humerus (Fig. 334) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment is slightly elevated under the coraco-acromial ligament by the muscles attached to the greater and lesser tuberosities; the lower fragment is drawn inward by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outward from the side by the Deltoid, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm outward and downward. To counteract the opposing muscles, and to keep the fragments in position, a conical-shaped pad should be placed with the apex in the axilla; while the forearm is flexed to an angle of 90 degrees the shoulder is padded with cotton, a shoulder-cap of plaster-of-Paris is applied to cover the shoulder, a portion of the chest and back, and the arm down to the external condyle (Scudder). The arm, with the elbow slightly forward, is bandaged to the side. In some cases a splint is placed between the axillary pad and the inner side of the arm.

In fracture of the shaft of the humerus below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity, the upper fragment being drawn inward by the first-mentioned muscles, and the lower fragment upward and outward by the Deltoid, producing shortening of the limb and a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture takes place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and are retained in that position by adopting the same means as in the preceding injury, or by the use of an internal angular splint with three short humeral splints.

In fractures of the shaft of the humerus immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occurs in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forward; but in oblique fracture the combined actions of the Biceps and Brachialis anticus muscles in front and the Triceps behind draw upward the lower fragment, causing it to glide over the upper fragment, either backward or forward, according to the direction of the fracture. Simple extension reduces the deformity, and the application of an internal angular splint and three short humeral splints will retain the fragments in apposition. Care should be taken not to raise the elbow, but the forearm and hand may be supported in a sling.

Fracture of the humerus (Fig. 335) above the condyle deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backward. If the direction of the fracture is oblique from above, downward and forward, the lower fragment is drawn upward by the Brachialis anticus and Biceps in front and the Triceps behind; and at the same time is drawn backward behind the upper fragment by the Triceps. This injury may be diagnostic from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact of the deformity being remedied by extension, on the discontinuance of which it is reproduced. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. If fracture occurs in the opposite direction to that shown in Fig. 335, the lower fragment is drawn upward and forward, causing a considerable prominence in front, and the upper fragment projects backward beneath the tendon of the Triceps muscle.

Fractures of the lower extremity of the humerus are spoken of as fractures in the neighborhood of the elbow-joint. The term includes fracture of the external condyle, of the internal condyle, at the base of the condyles, and T- or Y-shaped fracture, the two condyles being separated from each other and from the shaft of the humerus. Such injuries are followed by great and rapid swelling. Whenever possible the x-rays are used to aid in diagnosis, and the patient is placed under ether, to set and dress the fracture.

In fracture of the inner condyle the fragment with the ulna passes up and back, and when

Fig. 334.—Fracture of the surgical neck of the humerus.
the forearm is extended the ulna projects posteriorly. The "carrying function" of the arm is lost, because the forearm deviates to the ulnar side.

In all cases of fracture of the lower end of the humerus, except fracture at the base of the condyles, effect reduction by traction upon the forearm, and supination, extension, and bending the forearm slowly into acute flexion. In transverse fracture above the condyles draw the forearm and the lower fragment downward and forward and push the upper fragment back. A case can be treated by maintaining a position of acute flexion (Jones's position) or by using an anterior angular splint. Allis and others treat in extension.

Fracture of the olecranon process (Fig. 336) is a frequent accident. The detached fragment is displaced upward, by the action of the Triceps muscle, from half an inch to two inches; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in relaxing the Triceps by extending the limb, and retaining it in the extended position by means of a long straight splint applied to the front of the arm; the fragments are thus brought into close apposition, and may be further approximated by drawing down the upper fragment. Union is generally ligamentous.

Fracture of the neck of the radius is an exceedingly rare accident, and is generally caused by direct violence. Its diagnosis is somewhat obscure, on account of the slight deformity visible, the injured part being surrounded by a large number of muscles; but the movements of pronation and supination are entirely lost. The upper fragment is drawn outward by the Supinator brevis, the extent of displacement being limited by the attachment of the orbicular ligament. The lower fragment is drawn forward and slightly upward by the Biceps, and inward by the Pronator radii teres, its displacement forward and upward being counteracted in some degree by the Supinator brevis. The treatment essentially consists in relaxing the Biceps, Supinator brevis, and Pronator radii teres muscles by flexing the forearm, and placing it in a position midway between pronation and supination, extension having been previously made so as to bring the parts in apposition.

In fracture of the radius below the insertion of the Biceps, but above the insertion of the Pronator radii teres, the upper fragment is strongly supinated by the Biceps and Supinator brevis, and at the same time drawn forward and flexed by the Biceps; the lower fragment is pronated and drawn inward toward the ulna by the pronators. Thus there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator radii teres (Fig. 337), the upper fragment is drawn upward by the Biceps and inward by the Pronator radii teres, holding a position midway between pronation and supination, and a degree of fulness in the upper half of the forearm is thus produced; the lower fragment is drawn downward and inward toward the ulna by the Pronator quadratus, and thrown into a state of pronation by the same muscle; at the same time, the Supinator longus, by elevating the styloid process, into which

![Fig. 335.—Fracture of the humerus above the condyles.](image)

![Fig. 336.—Fracture of the olecranon.](image)
it is inserted, will serve to depress the upper end of the lower fragment still more toward the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow: well-padded splints should be applied on both sides of the forearm from the elbow to the wrist; the hand being allowed to fall, will, by its own weight, counteract the action of the Pronator quadratus and Supinator longus, and elevate the lower fragment to the level of the upper one.

In fracture of the shaft of the ulna the upper fragment retains its usual position, but the lower fragment is drawn outward toward the radius by the Pronator quadratus, producing a well-marked depression at the seat of fracture and some fulness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the shafts of the radius and ulna together the lower fragments are drawn upward, sometimes forward, sometimes backward, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on the dorsal or palmar surface of the forearm; at the same time the two fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation: the upper fragment of the radius is drawn upward and inward by the Biceps and Pronator radii teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the lower end of the radius (Colles' fracture) (Fig. 338) the displacement which is produced is very considerable, and bears some resemblance to dislocation of the carpus backward, from which it should be carefully distinguished. The lower fragment is displaced backward and upward, but this displacement is probably due to the force of the blow driving the portion of the bone into this position and not to any muscular influence. The upper fragment projects forward, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of the forearm, immediately above the carpus, from the flexor tendons being thrust forward. This fracture may be distinguished from dislocation by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected; at the same time, on extension being discontinued, the parts immediately resume their deformed appearance. The age of the patient will also assist in determining whether the injury is fracture or separation of the epiphysis. Reduction is effected by hyperextension, longitudinal traction, and forced flexion. The posterior straight splint with suitable pads is the best dressing.

I. MUSCLES AND FASCIAE OF THE ILIAC REGION.

**Dissection.**—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

**Iliac Fascia (fascia iliaca).**—The iliac fascia\(^1\) is the aponeurotic layer which lines the back part of the abdominal cavity, and covers the Psoas and Iliacus muscles throughout their whole extent. It is thin above, and becomes gradually thicker below as it approaches the crural arch.

The **Portion Covering the Psoas** is attached, above, to the ligamentum arcuatum internum; internally, by a series of arched processes to the intervertebral substances and prominent margins of the bodies of the vertebrae, and to the upper part of the sacrum, the intervals so left, opposite the constricted portions of the bodies, transmitting the lumbar arteries and veins and filaments of the sympathetic cord. Externally, above the crest of the ilium, this portion of the iliac fascia is continuous with the anterior lamella of the lumbar fascia, but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The **Portion Investing the Iliacus** is connected externally to the whole length of the inner border of the crest of the ilium, and internally to the brim of the true pelvis, where it is continuous with the peristemeum; and at the ilio-pectineal eminence it receives the tendon of insertion of the Psoas parvus, when that muscle exists. External to the femoral vessels, this fascia is intimately connected to the posterior margin of Poupart’s ligament, and is continuous with the fascia transversalis. Immediately to the outer side of the femoral vessels the fascia iliaca is prolonged backward and inward from Poupart’s ligament as a band, the **ilio-pectineal ligament**, which is attached to the ilio-pectineal eminence. This ligament divides the space between Poupart’s ligament and the innominate bone into two parts, the inner of which (lacuna vasorum) transmits the femoral vessels, and contains the

\(^1\) The student must not confound this fascia with the *iliac portion of the fascia lata* (see p. 515).
THE ILIAC REGION

509

margin of Gimbernat's ligament and also the femoral ring; the outer (*laeuna musculorum*) the ilio-psoas and the anterior crural nerve (Fig. 340). Internal to the vessels the iliac fascia is attached to the ilio-pectineal line behind the conjoined tendon, where it is again continuous with the transversalis fascia; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends behind them, forming the posterior wall of the femoral sheath. This portion of the iliac fascia which passes behind the femoral vessels is also attached to the ilio-pectineal line beyond the limits of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the fascia lata of the thigh. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus behind it; it is separated from the peritoneum by a quantity of loose areolar tissue. The femoral or crural sheath (*fascia cruris*)

![Fig. 340.—Poupart's ligament and the relation of the parts passing beneath it. (Poirier and Charpy.)](image)

formed by the transversalis fascia in front of the vessels and the iliac fascia back of them. The fasciae join to the inner side of the femoral vein, a space, the femoral canal, intervening between the vein and the junction.

Between the femoral vein and the edge of Gimbernat's ligament is the femoral or crural ring (*annulus femoralis*) (Fig. 342). The crural or femoral canal (*canalis femoralis*) is the interval between the femoral vein and the inner wall of the femoral (crural) sheath. This canal extends from the femoral ring to the saphenous opening. The femoral ring is closed by the septum crurale of Cloquet (*septum femorale [Cloqueti]*) , which is a process of transversalis fascia.

The Psoas Magnus (*m. psoas major*) (Fig. 343) is a long fusiform muscle placed on the side of the lumbar region of the spine and the margin of the pelvis. It arises from the front of the bases and lower borders of the transverse processes of the
lumbar vertebrae by five fleshy slips; also from the sides of the bodies and the corresponding intervertebral substances of the last dorsal and all the lumbar vertebrae. The muscle is connected to the bodies of the vertebrae by five slips; each slip is attached to the upper and lower margins of two vertebrae, and to the intervertebral substance between them, the slips themselves being connected by the tendinous arches which extend across the constricted part of the bodies, and beneath which pass the lumbar arteries and veins and filaments of the sympathetic cord. These tendinous arches also give origin to muscular fibres, and protect the blood-vessels and nerves from pressure during the action of the muscle. The first slip is attached to the contiguous margins of the last dorsal and first lumbar vertebrae; the last to the contiguous margins of the fourth and fifth lumbar vertebrae, and to the intervertebral substance. From these points the muscle descends across the rim of the pelvis, and, diminishing gradually in size, passes beneath Poupart's ligament, and terminates in a tendon which, after receiving nearly the whole of the fibres of the Iliacus, is inserted into the lesser trochanter of the femur.

**Relations.**—In the **lumbar region**: by its anterior surface, which is placed behind the peritoneum, with the iliac fascia, the ligamentum arcuatum internum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, genito-crural nerve, and the colon. In many cases the vermiform appendix rests upon the Psoas muscle (page 511). By its posterior surface, with the transverse processes of the lumbar vertebrae and the Quadratus lumborum muscle, from which it is separated by the anterior lamella of the lumbar fascia. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its inner side the muscle is in relation with the bodies of the lumbar vertebrae, the lumbar arteries, the ganglia of the sympathetic nerve, and their branches of communication with the spinal nerves; the lumbar glands; the vena cava inferior on the right and the aorta on the left side, and along the brim of the pelvis with the external iliac artery. In the thigh it is in relation, in front, with the fascia lata; behind, with the capsular ligament of the hip, from which it is separated by a synovial bursa (*bursa iliopsoas*), which frequently communicates with the cavity of the joint through an opening of variable size; between the tendon and part of the lesser trochanter is the *bursa iliaca subtendinea*; by its inner border, with the Pectineus and internal circumflex artery, and also with the femoral artery, which slightly overlaps it: by its outer border, with the anterior crural nerve and Iliacus muscle.

The **Psoas Parvus** (*m. psoas minor*) (Fig. 343) is a long slender muscle placed in front of the Psoas magnus. It arises from the sides of the bodies of the last dorsal and first lumbar vertebrae and from the intervertebral substance between them. It forms a small flat muscular bundle, which terminates in a long flat tendon inserted into the ilio-pectineal eminence, and, by its outer border, into the iliac fascia. This muscle is often absent, and, according to Cruveilhier, is sometimes double.

**Relations.**—It is covered by the peritoneum, and, at its origin, by the ligamentum arcuatum internum; it rests on the Psoas magnus.

The **Iliacus** (Fig. 343) is a flat, triangular muscle which fills up the whole of the iliac fossa. It arises from the upper two-thirds of this fossa and from the inner margin of the crest of the ilium; behind, from the ilio-lumbar ligament and base of the sacrum; in front, from the anterior superior and anterior inferior spinous processes of the ilium, from the notch between them. The fibres converge to be inserted into the outer side of the tendon of the Psoas, some of them being prolonged on to the shaft of the femur for about an inch below and in front of the lesser trochanter. The most external fibres are inserted into the capsule of the

---

1 The Psoas magnus, Psoas parvus, and Iliacus are regarded by His and others as a single muscle, the *Ilio-psoas* (Fig. 340).
THE Iliac REGION

511

hip-joint. If these fibres are separate they constitute the Ilio-capsularis muscle or the Iliacus minor.

Relations.—Within the abdomen: by its anterior surface, with the iliac muscle, which separates the muscle from the peritoneum, and with the external cutaneous nerve; on the right side, with the cecum; on the left side, with the sigmoid flexure of the colon; by its posterior surface, with the iliac fossa; by its inner border, with the Psoas magnus and anterior crural nerve. In the thigh, it is in relation, by its anterior surface, with the fascia lata, the Rectus and Sartorius muscles, and the profunda femoris artery; behind, with the capsule of the hip-joint, a synovial bursa common to it and the Psoas magnus being interposed.

Nerves.—The Psoas magnus is supplied by the anterior branches of the second and third lumbar nerves; the Psoas parvus, when it exists, is supplied by the anterior branch of the first lumbar nerve; and the Iliacus by the anterior branches of the second and third lumbar nerves through the anterior crural.

Actions.—The Psoas and Iliacus muscles, acting from above, flex the thigh upon the pelvis. Acting from below, the femur being fixed, the muscles of both sides bend the lumbar portion of the spine and pelvis forward. They also serve to maintain the erect position, by supporting the spine and pelvis upon the femur, and assist in raising the trunk when the body is in the recumbent posture.

The Psoas parvus is a tensor of the iliac fascia. It assists in flexing the lumbar spine laterally, the pelvis being its fixed point.

Surgical Anatomy.—There is no definite septum between the portions of the iliac fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseo-fibrous cavity, which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

Abscess within the sheath of the Psoas muscle (psoas abscess) is generally due to tuberculous caries of the bodies of the lower dorsal or of the lumbar vertebrae. When the disease is in the dorsal region, the matter tracts down the posterior mediastinum, in front of the bodies of the vertebrae, and, passing beneath the ligamentum arcuatum internum, enters the sheath of the Psoas muscle, down which it passes as far as the pelvic brim; it then gets beneath the iliac portion of the fascia and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament into the thigh, to the outer side of the femoral vessels. It thus follows that a Psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the Psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebrae are the seat of the disease, the matter finds its way directly into the substance of the muscle. If a Psoas abscess forms the muscular fibres are destroyed, and the nervous cords contained in the abscess are isolated and exposed in its interior; the femoral vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All Psoas abscesses do not, however, pursue this course: the matter may leave the muscle above the crest of the ilium, and, tracking backward, may point in the loin (lumbar abscess); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great sacro-sciatic notch, discharge itself on the back of the thigh; it may open into the bladder or find its way into the perineum, or it may pass down the thigh to the popliteal space or even lower. Strain of the Psoas muscle is not unusual, and induces pain which may be mistaken for appendicitis. The bursa beneath the tendon of the Psoas and Iliacus and the hip-joint or that between the tendon and the lesser trochanter may greatly enlarge and produce pain and dissenblance. Byron Robinson pointed out that trauma of the Psoas muscle may be an important factor in the etiology of appendicitis, trauma may induce periappendicular adhesions and adhesions interfere with the circulation of blood and feaces. Robinson says, in the previously quoted article, that in 46 per cent. of men and in 20 per cent. of women the appendix rests on the Psoas muscle.

Subcureus.

Dissection.—To expose the muscles and fasciae in this region, make an incision along Poupart's ligament, from the anterior superior spine of the ilium to the spine of the os pubis; a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciae should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia and Scarpa's triangle, the incisions for the dissection of which are marked out in Fig. 341.

Superficial Fascia.—The superficial fascia forms a continuous layer over the whole of the thigh. It consists of areolar tissue, containing in its meshes much fat, and is capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb: in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen and the back. Internally it is continuous with the superficial fascia of the perineum. The deep layer of the superficial fascia is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening (Fig. 342) in the fascia lata, being closely united to the margins of the opening, and is connected to the sheath of the femoral vessels by its under surface. The portion of the fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the cribiform fascia (fascia cribrosa), the openings for these vessels having been likened to the holes in a sieve. The cribiform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as part of the fascia lata, but is usually considered (as in this work) as belonging to the superficial fascia. It is not until the cribiform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. Mr.
Caliender, however, speaks of cases in which, probably as the result of pressure from enlarged inguinal lymphatic glands, the fascia has become atrophied, and a saphenous opening exists independent of dissection. A femoral hernia in passing through the saphenous opening receives the cribiform fascia as one of its coverings. A large subcutaneous bursa (bursa pra'patellaris subcutanea) is found in the superficial fascia over the patella, and another (bursa trochanterica subcutanea) in the superficial fascia over the great trochanter.

**Deep Fascia or Fascia Lata** (Fig. 342).—The deep fascia of the thigh is exposed on the removal of the superficial fascia, and is named, from its great extent, the *fascia lata*; it forms a uniform investment for the whole of this region of the limb, but varies in thickness in different parts; thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and the Tensor fasciae latae is inserted between its layers: it is very thin behind, and at the upper and inner part where it covers the Adductor muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the Biceps externally, from the Sartorius internally, and from the Quadriceps extensor in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; externally, to the crest of the ilium; in front, to Poupart's ligament and to the body of the os pubis; and internally, to the descending ramus of the os pubis, to the ramus and tuberosity of the ischium, and to the lower border of the great sacro-sciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius muscle to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle. At the lower border of the muscle the two layers reunite. Externally the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata arising from the front part of the crest of the ilium, cor-
THE MUSCLES AND FASCIAE

responding to the origin of the Tensor fasciae femoris, passes down the outer side of the thigh as two layers, one superficial to and the other beneath this muscle. The deep layer is a continuation of the tendinous fibres of the Gluteus maximus muscle and the superficial layer is chiefly a continuation of the tendinous fibres of the Tensor fasciae femoris, but receives some fibres from the fascia covering the Gluteus medius muscle. These layers at the lower end of the muscle become blended into a thick and strong band, having first received the insertion of the muscle. This band is continued downward, under the name of the ilio-tibial band (tractus iliotibialis [Maisiani]), to be inserted into the external tuberosity of the tibia. A strengthening band of transverse fibres is placed in the gluteal groove or sulcus (sulcus glutaeus) and another is placed across the roof of the popliteal space. Below, the fascia lata is attached to all the prominent points around the knee-joint—viz., the condyles of the femur, tuberosities of the tibia, and head of the fibula. On each side of the patella it is strengthened by transverse fibres given off from the lower part of the Vasti muscles, which are attached to and support this bone. Of these the outer fibres are the stronger, and are continuous with the ilio-tibial band. From the inner surface of the fascia lata are given off two strong intermuscular septa, which are attached to the whole length of the linea aspera and its prolongations above and below: the external intermuscular septum (septum intermusculare laterale) is the stronger. It extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps behind, and gives partial origin to these muscles; the internal intermuscular septum (septum intermusculare mediale), the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these there are numerous smaller septa, separating the individual muscles and enclosing each in a distinct sheath. At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared off: it transmits the internal saphenous vein and other smaller vessels, and is termed the saphenous opening (fossa ovalis) (Fig. 342). This opening is covered by a portion of the deep layer of the

superficial fascia, the *cribiform fascia*. In order more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions—an iliac portion and a pubic portion.

**Iliac Portion.**—The iliac portion, the *superficial layer of the fascia lata* or the *Sartorial portion of the fascia lata*, is all that part of the fascia lata on the outer side of the saphenous opening. It is attached, externally, to the crest of the ilium and its anterior superior spine, to the whole length of Poupart’s ligament as far internally as the spine of the os pubis, and to the pectineal line in conjunction with Gimbernat’s ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the *falciform process* or the *falciform margin of Burns* (*margo falciformis*), or the *superior cornu of the saphenous opening* (*cornu superius*). This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels: to its edge is attached the cribiform fascia; and, below, it is continuous with the pubic portion of the fascia lata. The *femoral ligament*, or the *ligament of Hey*, is the point at which the falciform process joins the base of Gimbernat’s ligament.

**Pubic Portion.**—The pubic portion, or the *pectineal portion*, or the *deep layer of the fascia lata*, is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion. The lower concave margin of the saphenous opening where the two layers of fascia are continuous is called the *inferior cornu* (*cornu inferius*). Traced upward, the pubic portion covers the surface of the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the iliac fascia. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous joins the femoral vein.¹

**Surgical Anatomy.**—The ilio-tibial band at a point between the crest of the ilium and the great trochanter is so tense that it is impossible to sink the fingers in deeply in this region. Dr. Allis points out that in fracture of the neck of the femur the great trochanter mounts toward the iliac crest, the ilio-tibial band relaxes, and the fingers can be sunk deeply into the space between the great trochanter and the iliac crest—Allis’s *sign*. Allis’s sign indicates shortening. A *Psoas present* usually points at the termination of the Psoas muscle, but the tuberculous matter may be directed down the thigh beneath the fascia lata, and it may reach the popliteal space or even lower.

The fascia should now be removed from the surface of the muscles. This may be effected by pinching it up between the forceps, dividing it, and separating it from each muscle in the course of its fibres.

The *Tensor Fasciae Femoris* (*m. tensor fasciae latae*, *m. tensor vaginae femoris*) (Fig. 343) arises from the anterior part of the outer lip of the crest of the ilium, and from the outer surface of the anterior superior spinous process, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius, and from the surface of the fascia covering the Gluteus medius. It is inserted between two layers of the fascia lata, about one-fourth down the outer side of the thigh. From the point of insertion the fascia is continued downward to the external tuberosity of the tibia as a thickened band, the *ilio-tibial band*.

**Relations.**—By its *superficial surface*, with the fascia lata and the integument; by its *deep surface*, with the Gluteus medius, Rectus femoris, and Vastus externus muscles, and the ascending branches of the external circumflex artery; by its *anterior border*, with the Sartorius, from which it is separated below by a triangular

¹ These parts will be again more particularly described with the anatomy of Hernia.
space, in which is seen the Rectus femoris; by its posterior border, with the Gluteus medius.

The Sartorius (Fig. 343), the longest muscle in the body, is flat, narrow, and ribbon-like; it arises by tendinous fibres from the anterior superior spinous process of the ilium and the upper half of the notch below it, passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur, and terminates in a tendon which, curving obliquely forward, expands into a broad aponeurosis, inserted in front of the Gracilis and Semitendinosus, into the upper part of the inner surface of the shaft of the tibia, nearly as far forward as the crest. The upper part of the tendon is curved backward over the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset is derived from the upper margin of this aponeurosis, which blends with the fibrous capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the outer side of a triangular space, Scarpa's triangle (trigonum femorale), the inner side of which is formed by the inner border of the Adductor longus, and the base, which is turned upward, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh the femoral artery lies first along the inner border, and then behind the Sartorius.

Relations.—By its superficial surface, with the fascia lata and integument; by its deep surface, with the Rectus, Iliacus, Vastus internus, anterior crural nerve, sheath of the femoral vessels, Adductor longus, Adductor magnus, Gracilis, Semitendinosus, long saphenous nerve, and internal lateral ligament of the knee-joint. Frequently there is a bursa (bursa m. sartorii propria) between the tendon of the Sartorius and the tendons of the Gracilis and Semimembranosus. It may be in communication with the bursa anserina.

The Quadriceps Extensor (m. quadriceps femoris) (Fig. 343) includes the four remaining muscles on the front of the thigh. It is the great Extensor muscle of the leg, forming a large fleshy mass which covers the front and sides of the femur, being united below into a single tendon, attached to the patella, and above subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, connected above with the ilium, is called the Rectus femoris, from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The portion on the outer side of the femur is termed the Vastus externus; that covering the inner side, the Vastus internus; and that covering the front of the femur, the Græreus.

The Rectus Femoris is situated in the middle of the anterior region of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: one, the anterior or straight, from the anterior inferior spinous process of the ilium; the other, the posterior or reflected tendon, from a groove above the brim of the acetabulum; the two unite at an acute angle and spread into an aponeurosis, which is prolonged downward on the anterior surface of the muscle and from which the muscular fibres arise.1 The muscle terminates in a broad and thick aponeurosis, which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted

---

1 Mr. W. R. Williams, in an interesting paper in the Journ. of Anat. and Phys., vol. xiii. p. 204, points out that the reflected tendon is the real origin of the muscle, and is alone present in early foetal life. The direct tendon is merely an accessory band of condensed fascia. The paper will well repay perusal, though in some particulars I think the description in the text more generally accurate.—Ed. of 15th English edition.
into the patella in common with the Vasti and Crureus. Between the tendon of origin and the acetabulum there is often a bursa (bursa m. recti femoris).

**Relations.**—By its superficial surface, with the anterior fibres of the Gluteus minimus, the Tensor fasciae femoris, the Sartorius, and the Iliacus; by its lower three-fourths, with the fascia lata. By its posterior surface, with the hip-joint, the external circumflex vessels, branches of the anterior crural nerve, and the Crureus and Vasti muscles.

The Vastus Externus (m. vastus lateralis) is the largest part of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the upper half of the anterior intertrochanteric line, to the anterior and inferior borders of the root of the great trochanter, to the outer lip of the gluteal ridge, and to the upper half of the outer lip of the linea aspera; this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part: this becomes contracted and thickened into a flat tendon, which is inserted into the outer border of the patella, blending with the great Extensor tendon, and giving an expansion to the capsule of the knee-joint. Some of the fibres run down by the side of the patella to the condyle of the tibia, and are called the retinacula patellae laterale.

**Relations.**—By its superficial surface, with the Rectus, the Tensor fasciae femoris, the fascia lata, and the tendon of the Gluteus maximus, from which it is separated by a synovial bursa. By its deep surface, with the Crureus, some large branches of the external circumflex artery and anterior crural nerve being interposed.

The Vastus Internus and Crureus appear to be inseparably united, but when the Rectus femoris has been reflected, a narrow interval will be observed extending upward from the inner border of the patella between the two muscles. Here they can be separated, and the separation should be continued upward as far as the lower part of the anterior intertrochanteric line, where, however, the two muscles are frequently continuous.

The Vastus Internus (m. vastus medialis) arises from the lower half of the anterior intertrochanteric line, the spiral line, the inner lip of the linea aspera, the upper part of the internal supra-condylar line, and the tendon of the Adductor magnus and the internal intermuscular septum. Its fibres are directed downward and forward, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is inserted into the inner border of the patella and the Quadriceps extensor tendon, an expansion being sent to the capsule of the knee-joint. Some of the fibres run down by the side of the patella to the condyle of the tibia and are called the retinacula patellae mediale.

The Crureus (m. vastus intermedius) arises from the front and outer aspect of the shaft of the femur in its upper two-thirds and from the lower part of the external intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the Quadriceps extensor tendon.

**Relations.**—The inner edge of the Crureus is in contact with the anterior edge of the Vastus internus, but when separated from each other, as directed above, the latter muscle is seen merely to overlap the inner aspect of the femoral shaft without taking any fibres of origin from it. The Vastus internus is partly covered by the Rectus and Sartorius, but where these separate near the knee it becomes superficial, and produces a well-marked prominence above the inner aspect of the knee. In the middle third of the thigh it forms the outer wall of Hunter's canal (canalis adductorius [Hunteri]), which contains the femoral vessels and the long saphenous nerve—the roof of the canal being formed by a strong fascia which extends from
the Vastus internus to the Adductores longus and magnus. The Crureus is almost completely hidden by the Rectus femoris and Vastus externus. The deep surface of the two muscles is in relation with the femur and Subcrureus muscles. A synovial bursa (bursa suprapatellaris) is situated between the femur and the portion of the Quadriceps extensor tendon above the patella; in the adult it communicates with the synovial cavity of the knee-joint.

The tendons of the different portions of the Quadriceps extensor unite at the lower part of the thigh, so as to form a single strong tendon, which is inserted into the upper part of the patella, some few fibres passing over it to blend with the Ligamentum patellae. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps; and the Ligamentum patellae, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle. A synovial bursa, the deep patellar bursa (bursa infrapatellaris profunda), is interposed between the tendon and the upper part of the tuberosity of the tibia; and another, the pre-patellar bursa (bursa prepatellaris subcutanea), is placed over the patella itself. This latter bursa often becomes enlarged, constituting "housemaid's knee."

The Subcrureus (m. articularis genu) is a small muscle, usually distinct from the Crureus, but occasionally blended with it, which arises from the anterior surface of the lower part of the shaft of the femur, and is inserted into the upper part of the cul-de-sac of the capsular ligament which projects upward beneath the Quadriceps for a variable distance. It sometimes consists of several separate muscular bundles.

Nerves.—The Tensor fasciae femoris is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through branches of the anterior crural.

Actions.—The Tensor fasciae femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct and to rotate the thigh inward. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur, and by means of the ilio-tibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next rotates the thigh outward. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, and hence received its name of Sartorius, or tailor's muscle (sartor, a tailor), because it was supposed to assist in crossing the legs in the squatting position. When the knee is bent the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inward. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh is fixed it will flex the pelvis. The Vastus internus draws the patella inward as well as upward.

Surgical Anatomy.—A few fibres of the Rectus muscle are liable to be ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as cricket thigh. The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor may be torn away from its insertion into the patella, or the tendon of the quadriceps may be ruptured about an inch above the bone. This accident is caused in the same manner that fracture of the patella by muscular action is produced—viz., by a violent muscular effort to prevent falling whilst the knee is in a position of semiflexion. A distinct gap can be
felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place. Sudden and powerful contraction of the Quadriceps extensor femoris is the cause of transverse fracture of the patella.

2. The Internal Femoral Region.

**Dissection.**—These muscles are at once exposed by removing the fascia from the forepart and inner side of the thigh. The limb should be abducted, so as to render the muscles tense and easier of dissection.

The **Gracilis** (Figs. 343, 346, and 349) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrowing and tapering below. It arises by a thin aponeurosis from the lower half of the margin of the symphysis and the anterior half of the pubic arch. The fibres pass vertically downward, and terminate in a rounded tendon which passes behind the internal condyle of the femur, and, curving round the inner tuberosity of the tibia, becomes flattened, and is inserted into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. The tendon of this muscle is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint it is separated from it by a synovial bursa (bursa anserina) common to it and the Semitendinosus muscle.

**Relations.**—By its superficial surface, with the fascia lata and the Sartorius below: the internal saphenous vein crosses it obliquely near its lower part, lying superficial to the fascia lata; the internal saphenous nerve emerges between its tendon and that of the Sartorius; by its deep surface, with the Adductor brevis and the Adductor magnus and the internal lateral ligament of the knee-joint.

The **Pectineus** (Fig. 343) is a flat, quadrangular muscle, situated at the anterior part of the upper and inner aspect of the thigh. It arises from the linea ilipectineal, and to a slight extent from the surface of the bone in front of it between the pectineal eminence and spine of the os pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downward, backward, and outward, to be inserted into a rough line leading from the lesser trochanter to the linea aspera.

**Relations.**—By its anterior surface, with the pubic portion of the fascia lata, which separates it from the femoral vessels and internal saphenous vein; by its posterior surface, with the capsular ligament of the hip-joint, the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed; by its outer border, with the Psoas, a cellular interval separating them, through which pass the internal circumflex vessels; by its inner border, with the margin of the Adductor longus. There is usually a bursa (bursa m. pectinei) between the pectineus and the tendon of the psoas and iliacus.

The **Adductor Longus** (Figs. 343 and 344), the most superficial of the three Adductors, is a flat triangular muscle lying on the same plane as the Pectineus. It arises, by a flat narrow tendon, from the front of the os pubis, at the angle of junction of the crest with the symphysis; and soon expands into a broad fleshy belly, which, passing downward, backward, and outward, is inserted, by an aponeurosis, into the linea aspera, between the Vastus internus and the Adductor magnus, with both of which it is usually blended.

**Relations.**—By its anterior surface, with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; by its posterior surface, with the Adductor brevis and magnus, the anterior branches of the obturator nerve, and
with the profunda artery and vein near its insertion; by its outer border, with the Pectineus; by its inner border, with the Gracillis.

The Pectineus and Adductor longus should now be divided near their origin, and turned downward, when the Adductor brevis and Obturator externus will be exposed.

The **Adductor Brevis** (Fig. 344) is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the body and descending ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres passing backward, outward, and downward, are inserted, by an aponeurosis, into the lower part of the line leading from the lesser trochanter to the linea aspera and the upper part of the same line, immediately behind the Pectineus and upper part of the Adductor longus.

**Relations.**—By its anterior surface, with the Pectineus, Adductor longus, profunda femoris artery, and anterior branches of the obturator nerve; by its posterior surface, with the Adductor magnus and posterior branch of the obturator nerve; by its outer border, with the internal circumflex artery, the Obturator externus, and conjoined tendon of the Psoas and Iliacus; by its inner border, with the Gracilis and Adductor magnus. This muscle is pierced, near its insertion, by the second or by the first and second perforating branches of the profunda femoris artery.

The Adductor brevis should now be cut away near its origin, and turned outward, when the entire extent of the Adductor magnus will be exposed.

The **Adductor Magnus** (Fig. 344) is a large triangular muscle forming a septum between the muscles on the inner and those on the back of the thigh. It arises from a small part of the descending ramus of the os pubis, from the ramus of the ischium, and from the outer margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are very short, horizontal in direction, and are inserted into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus. They are considered by some a distinct muscle and called the **Adductor minimus**. The fibres taking origin from the ramus of the ischium are directed downward and outward.
with different degrees of obliquity, to be *inserted*, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The **internal portion** of the muscle, consisting principally of those fibres which *arise* from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is *inserted* into the Adductor tubercle on the inner condyle of the femur, being connected by a fibrous expansion to the line leading upward from the tuberclcle to the linea aspera. Between the two portions of the muscle an interval is left, tendinous in front, fleshy behind, for the passage of the femoral vessels from Hunter’s canal into the popliteal space. The **external portion** of the muscle at its attachment to the femur presents three or four osseo-aponeurotic openings, formed by tendinous arches attached to the bone, from which muscular fibres arise. The three superior of these apertures are for the three perforating arteries, and the fourth, when it exists, is for the terminal branch of the profunda.

**Relations.**—By its *anterior surface*, with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve; by its *posterior surface*, with the great sciatic nerve, the Gluteus maximus, Biceps, Semitendinosus, and Semimembranosus. By its *superior* or *shortest border* it lies parallel with the Quadratus femoris, the internal circumflex artery passing between them; by its *internal* or *longest border*, with the Gracilis, Sartorius, and fascia lata; by its *external* or *attached border* it is inserted into the femur behind the Adductor brevis and Adductor longus, which separate it from the Vastus internus, and in front of the Gluteus maximus and short head of the Biceps, which separate it from the Vastus externus.

**Nerves.** The three Adductor muscles and the Gracilis are supplied by the third and fourth lumbar nerves through the obturator nerve; the Adductor magnus receiving an additional branch from the sacral plexus through the great sciatic. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the anterior crural, and by the accessory obturator, from the third lumbar, when it exists. Occasionally it receives a branch from the obturator nerve.  

**Actions.**—The Pectineus and three Adductors adduct the thigh powerfully; they are especially used in horse exercise, the flanks of the horse being grasped between the knees by the actions of these muscles. In consequence of the obliquity of their insertion into the linea aspera they rotate the thigh outward, assisting the external Rotators, and when the limb has been abducted they draw it inward, carrying the thigh across that of the opposite side. The Pectineus and Adductor brevis and longus assist the Psoas and Iliacus in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forward the hinder limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inward; it is also an adductor of the thigh. If the lower extremities are fixed, these muscles may take their fixed point from below and act upon the pelvis, serving to maintain the body in an erect posture, or, if their action is continued, to flex the pelvis forward upon the femur.

**Hunter’s Canal** (*canalis adductorius [Hunteri]*) extends from the apex of Scarpa’s triangle to the opening in the Adductor magnus muscle. The antero-internal boundary or roof of Hunter’s canal is the Sartorius and the aponeurotic expansion from the Adductors to the Vastus internus. It is bounded externally by the Vastus internus. The Adductor longus and Magnus constitute its floor or the postero-internal boundary. The canal contains the femoral artery, femoral vein, the long saphenous nerve, and the nerve to the Vastus internus. The anterior opening of Hunter’s canal is called the *hiatus tendineus*.

---

1 Professor Paterson describes the Pectineus as consisting of two incompletely separated strata, of which the outer or dorsal stratum, which is constant, is supplied by the anterior crural nerve, or in its absence by the accessory obturator, with which it is intimately related; while the inner or ventral stratum, when present, is supplied by the obturator nerve.—Journ. of Anat. and Phys., vol. xxvi. p. 43.—Ed. of 15th English edition.
**Surgical Anatomy.**—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon to be ruptured by suddenly gripping the saddle. Occasionally, especially in cowboys and cavalry soldiers, the tendon of insertion of the Adductor magnus may become ossified, constituting the rider's bone.

**THE MUSCLES AND FASCIAE OF THE HIP.**

### 3. The Gluteal Region (Figs. 346, 347).

- **Gluteus maximus.**
- **Obturator internus.**
- **Gluteus medius.**
- **Gemellus superior.**
- **Gluteus minimus.**
- **Gemellus inferior.**
- **Pyriformis.**
- **Quadratus femoris.**
- **Obturator externus.**

**Dissection** (Fig. 345).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum, and thence downward to the tip of the coccyx, and carry a second incision from that point obliquely downward and outward to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The **Gluteus Maximus** (*m. gluteus maximus*) (Fig. 346), the most superficial muscle in the gluteal region, is a very broad and thick, fleshy mass of a quadrilateral shape, which forms the prominence of the buttock. Its large size is one of the most characteristic points in the muscular system of man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscular fasciculi lying parallel with one another, and collected together into large bundles, separated by deep cellular intervals. It arises from the superior curved line of the ilium and the portion of bone, including the crest, immediately above and behind it; from the posterior surface of the lower part of the sacrum, the side of the coccyx, the aponeurosis of the Erector spinae muscle, the great sacro-sciatic ligament, and the fascia covering the Gluteus medius. The fibres are directed obliquely downward and outward; those forming the upper and large portion of the muscle, together with the superficial fibres of the lower portion, terminate in a thick tendinous lamina, which passes across the great trochanter and is inserted into the fascia lata covering the outer side of the thigh; the deeper fibres of the lower portion of the muscles are inserted into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.
Several synovial bursæ are found in relation with this muscle. One of these (bursa trochanterica m. glutæi maximi), of large size, and generally multilocular, separates it from the great trochanter. A second (bursa ischiadica m. glutæi maximi), often wanting, is situated on the tuberosity of the ischium. A third bursa is found between the tendon of this muscle and the Vastus externus. Two or three small bursæ (bursae glutæojemorales) are placed between the tendon of the muscle and the gluteal ridge.

Relations.—By its superficial surface, with a thin fascia, which separates it from the subcutaneous tissue; by its deep surface, from above downward, with the ilium, sacrum, coccyx, and great sacro-sciatic ligament, part of the Gluteus medius, Pyriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origin of the Biceps, Semitendinosus, Semimembranosus, and Adductor magnus muscles. The superficial part of the gluteal artery reaches the deep surface of the muscle by passing between the Pyriformis and the Gluteus medius; the sciatic and internal pudic vessels and nerves and muscular branches from the sacral plexus issue from the pelvis below the Pyriformis. The first perforating artery and the terminal branches of the internal circumflex artery are also found under cover of the muscle. Its upper border is thin, and connected with the Gluteus medius by the fascia lata. Its lower border is free and prominent.

Dissection.—Divide the Gluteus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Gluteus medius and External rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outward; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The Gluteus Medius (m. glutæus medius) (Fig. 346) is a broad, thick, radiated muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus; its anterior two-thirds by the fascia lata, which separates it from the integument. It arises from the outer surface of the ilium, between the superior and middle curved lines, and from the outer lip of that portion of the crest which is between them; it also arises from the dense fascia, the gluteal aponeurosis, covering its outer surface. The fibres converge to a strong flattened tendon which is inserted into the oblique line which traverses the outer surface of the great trochanter. A synovial bursa (bursa trochanterica m. glutæi medii anterior) separates the tendon of the muscle from the summit of the great trochanter. There is frequently a bursa (bursa trochanterica m. glutæi medii posterior) between the tendons of the Gluteus medius and Pyriformis.

Relations.—By its superficial surface, with the Gluteus maximus behind, the Tensor fasciæ femoris and deep fascia in front; by its deep surface, with the Gluteus minimus and the gluteal vessels and superior gluteal nerve. Its anterior border is blended with the Gluteus minimus. Its posterior border lies parallel with the Pyriformis, the gluteal vessels intervening.

This muscle should now be divided near its insertion and turned upward, when the Gluteus minimus will be exposed.

The Gluteus Minimus (m. glutæus minimus) (Fig. 346), the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the middle and inferior curved lines, and behind, from the margin of the great sacro-sciatic notch; the fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is inserted into an impression on the anterior border of the great trochanter.
Relations.—By its superficial surface, with the Gluteus medius and the gluteal vessels and superior gluteal nerve; by its deep surface, with the ilium, the reflected tendon of the Rectus femoris, and the capsular ligament of the hip-joint. Its anterior margin is blended with the Gluteus medius; its posterior margin is in contact and sometimes joined with the tendon of the Pyriformis. There is a synovial bursa (bursa m. glutæi minimi) between the tendon of the Gluteus minimus and the great trochanter.

The Pyriformis (m. piriformis) (Figs. 346 and 347) is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis at its posterior part and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also from the groove leading from the foramina: a few fibres also arise from the margin of the great sacro-sciatic foramen and from the anterior surface of the great sacro-sciatic ligament. The muscle passes out of the pelvis through the great sacro-sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the great trochanter, behind, but often partly blended with, the tendon of the Obturator internus and Gemelli muscles.

Relations.—By its anterior surface, within the pelvis, with the Rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels; external to the pelvis, with the posterior
surface of the ischium and the capsular ligament of the hip-joint; by its posterior surface, within the pelvis, with the sacrum, and external to it, with the Gluteus maximus; by its upper border, with the Gluteus medius, from which it is separated by the gluteal vessels and superior gluteal nerve; by its lower border, with the Gemellus superior and Coccygeus, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles. There is usually a bursa (bursa m. piriformis) between the tendon of the pyriformis and the ilium.

The Obturator Membrane (membrana obturatoria) (Fig. 215) is a thin layer of interlacing fibres which closes almost completely the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischio-pubic ramus, below and internal to the margin of the foramen. It presents at its upper and outer part a small canal, obturator canal (canalis obturatorius) for the passage of the obturator vessels and nerve. Both obturator muscles are connected with this membrane.

Dissection.—The next muscle, as well as the origin of the Pyriformis, can only be seen when the pelvis is divided and the viscera removed.

The Obturator Internus (Figs. 346 and 347), like the preceding muscle, is situated partly within the cavity of the pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the anterior and external wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the descending ramus of the os pubis and the ramus of the ischium, and at the side to the inner surface of the innominate bone below and behind the pelvic brim, reaching from the upper part of the great sacro-scatic foramen above and behind to the thyroid foramen below and in front. It also arises from the inner surface of the obturator membrane except at its posterior part, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve and to a slight extent from the obturator layer of the pelvic fascia, which covers it. The fibres converge rapidly, and are directed backward and downward, and terminate in four or five tendinous bands, which are found on its deep surface; these bands are reflected at a right angle over the inner surface of the tuberosity of the ischium, which is grooved for their reception; the groove is covered with cartilage, and lined by a synovial bursa (bursa m. obturatoris interni). The muscle leaves the pelvis by the lesser sacro-scatic foramen; and the tendinous bands unite into a single flattened tendon, which passes horizontally outward, and, after receiving the attachment of the Gemelli, is inserted into the forepart of the inner surface of the great trochanter in front of the Obturator externus. A synovial bursa, narrow and elongated in form, is usually found between the tendon of this muscle and the capsular ligament of the hip: it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium, the two forming a single sac.

In order to display the peculiar appearances presented by the tendon of this muscle, it must be divided near its insertion and reflected inward.

Relations.—Within the pelvis this muscle is in relation, by its anterior surface, with the obturator membrane and inner surface of the anterior wall of the pelvis; by its posterior surface, with the pelvic and obturator fasciae, which separate it from the Levator ani; and it is crossed by the internal pudic vessels and nerve. This surface forms the outer boundary of the ischio-rectal fossa (Fig. 339). External to the pelvis it is covered by the Gluteus maximus, is crossed by the great sciatic nerve, and rests on the back part of the hip-joint. As the tendon of the Obturator internus emerges from the lesser sacro-scatic foramen it is over-
lapped by the two Gemelli, while nearer its insertion the Gemelli pass in front of it and form a groove in which the tendon lies.

The Gemelli (Fig. 346) are two small muscular fasciculi, accessories to the tendon of the Obturator internus, which is received into a groove between them. They are called superior and inferior.

The Gemellus Superior, the smaller of the two, arises from the outer surface of the spine of the ischium, and, passing horizontally outward, becomes blended

with the upper part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter. This muscle is sometimes wanting.

Relations.—By its superficial surface, with the Gluteus maximus and the sciatic vessels and nerves; by its deep surface, with the capsule of the hip-joint; by its
upper border, with the lower margin of the Pyriformis; by its lower border, with the tendon of the Obturator internus.

The Gemellus Inferior arises from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon, and, passing horizontally outward, is blended with the lower part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter.

Relations.—By its superficial surface, with the Gluteus maximus and the sciatic vessels and nerves; by its deep surface, with the scapular ligament of the hip-joint; by its upper border, with the tendon of the Obturator internus; by its lower border, with the tendon of the Obturator externus and Quadratus femoris.

The Quadratus Femoris (Fig. 346) is a short, flat muscle, quadrilateral in shape (hence its name), situated between the Gemellus inferior and the upper margin of the Adductor magnus. It arises from the upper part of the external lip of the tuberosity of the ischium, and, proceeding horizontally outward, is inserted into the upper part of the linea quadrata; that is, the line which crosses the posterior intertrochanteric line. A synovial bursa is often found between the under surface of this muscle and the lesser trochanter, which it covers.

Relations.—By its posterior surface, with the Gluteus maximus and the sciatic vessels and nerves; by its anterior surface, with the tendon of the Obturator externus and trochanter minor and with the capsule of the hip-joint; by its upper border, with the Gemellus inferior. Its lower border is separated from the Adductor magnus by the terminal branches of the internal circumflex vessels.

Dissection.—In order to expose the next muscle (the Obturator externus) it is necessary to remove the Psoas, Iliacus, Pectineus, and Adductor brevis and longus muscles from the front
and inner side of the thigh, and the Gluteus maximus and Quadratus femoris from the back part. Its dissection should, consequently, be postponed until the muscles of the anterior and internal femoral regions have been explained.

The **Obturator Externus** (Figs. 347 and 348) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It *arises* from the margin of bone immediately around the inner side of the obturator foramen—viz., from the body and ramus of the os pubis and the ramus of the ischium; it also arises from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres from the pubic arch extend on to the inner surface of the bone, from which they obtain a narrow origin between the margin of the foramen and the attachment of the membrane. The fibres converging pass backward, outward, and upward, and terminate in a tendon which runs across the back part of the hip-joint, and is *inserted* into the digital fossa of the femur.

**Relations.**—By its *anterior surface*, with the Psoas, Iliacus, Pectineus, Adductor magnus, and Adductor brevis; and more externally, with the neck of the femur and capsule of the hip-joint. The obturator artery and vein lie between this muscle and the obturator membrane; the superficial part of the obturator nerve lies above the muscle, and the deep branch perforates it; by its *posterior surface*, with the obturator membrane and Quadratus femoris.

**Nerves.**—The Gluteus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the fourth and fifth lumbar and first sacral nerves through the superior gluteal; the Pyriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerve; the Gemellus superior and Obturator internus by the fifth lumbar and first and second sacral nerves, and the Obturator externus by the second, third, and fourth lumbar nerves through the obturator.

**Actions.**—The Gluteus maximus, when it takes its fixed point from the pelvis, extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the whole trunk upon the head of the femur, which is especially obvious in standing on one leg. Its most powerful actions are to hold the head of the femur in close approximation to the acetabulum in walking and to cause the body to regain the erect position after stooping by drawing the pelvis backward, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the ilio-tibial band it steadies the femur on the articular surface of the tibia during standing, when the Extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and external rotator of the limb. The Gluteus medius and minimus abduct the thigh when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciae femoris. Their anterior fibres, by drawing the great trochanter forward, rotate the thigh inward, in which action they are also assisted by the Tensor fasciae femoris. The remaining muscles are powerful rotators of the thigh outward. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotators cease, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outward. When the femur is fixed, the Pyriformis and Obturator muscles serve to draw the pelvis forward if it has been inclined backward, and assist in steadying it upon the head of the femur.

**Surgical Anatomy.**—The fascia over the gluteal region is extremely dense and an abscess beneath it may pass far down into the thigh.
4. The Posterior Femoral Region.

(Hamstring muscles.)

Dissection (Fig. 345).—Make a vertical incision along the middle of the back of the thigh, from the lower fold of the buttock to about three inches below the back of the knee-joint, and there connect it with a transverse incision, carried from the inner to the outer side of the leg. Make a third incision transversely at the junction of the middle with the lower third of the thigh. The integument having been removed from the back of the knee, and the boundaries of the popliteal space having been examined, the removal of the integument from the remaining part of the thigh should be continued, when the fascia and muscles of this region will be exposed.

The Biceps or Biceps Flexor Cruris (m. biceps femoris) is a large muscle, of considerable length, situated on the posterior and outer aspect of the thigh (Figs. 346 and 349). It arises by two heads. One, the long head (caput longum), arises from the lower and inner impression on the back part of the tuberosity
of the ischium, by a tendon common to it and the Semitendinosus, and from the lower part of the great sacro-sciatic ligament. Between this tendon of origin and the Semimembranosus there is often a bursa (bursa m. bicipitis femoris superior). The *femoral*, or *short head* (caput breve), arises from the outer lip of the linea aspera, between the Adductor magnus and Vastus externus, extending up almost as high as the insertion of the Gluteus maximus; from the outer prolongation of the linea aspera to within two inches of the outer condyle, and from the external intermuscular septum. The fibres of the long head form a fusiform belly, which, passing obliquely downward and a little outward, terminates in an aponeurosis which covers the posterior surface of the muscle, and receives the fibres of the short head; this aponeurosis becomes gradually contracted into a tendon, which is inserted into the outer side of the head of the fibula, and by a small slip into the lateral surface of the external tuberosity of the tibia. At its insertion the tendon divides into two portions, which embrace the long external lateral ligament of the knee-joint. From the posterior border of the tendon a thin expansion is given off to the fascia of the leg. The tendon of this muscle forms the *outer hamstring*. Sometimes there is a bursa (bursa bicipitogastronemialis) between the tendon of insertion of the Biceps and the origin of the Gastrocnemius, and there is a bursa (bursa m. bicipitis femoris inferior) between the tendon of the biceps and the external lateral ligament.

**Relations.**—By its superficial surface, with the Gluteus maximus and the small sciatic nerve, the fascia lata, and integument. By its deep surface, with the Semimembranosus, Adductor magnus, and Vastus externus, the great sciatic nerve, and, near its insertion, with the external head of the Gastrocnemius, the Plantaris, the superior external articular artery, and the external popliteal nerve.

The **Semitendinosus** (Figs. 346 and 349), remarkable for the great length of its tendon, is situated at the posterior and inner aspect of the thigh. It arises from the lower and inner impression on the tuberosity of the ischium by a tendon common to it and the long head of the Biceps; it also arises from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about three inches after their origin. There is a bursa (bursa m. bicipitis femoris superior) between the tendons of origin of the Biceps and Semitendinosus on one side and the tendon of origin of the Semimembranosus on the other. The Semitendinosus is a fusiform muscle, which, passing downward and inward, terminates a little below the middle of the thigh in a long round tendon which lies along the inner side of the popliteal space, then curves around the inner tuberosity of the tibia, and is inserted into the upper part of the inner surface of the shaft of that bone nearly as far forward as its anterior border. At its insertion it gives off from its lower border a prolongation to the deep fascia of the leg. This tendon lies behind the tendon of the Sartorius, and below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscles. The **bursa anserina** lies between the tendon of the Semitendinosus and the tibia. This bursa was referred to in speaking of the Gracilis, p. 519.

**Relations.**—By its superficial surface, with the Gluteus maximus and fascia lata; by its deep surface, with the Semimembranosus, Adductor magnus, inner head of the Gastrocnemius, and internal lateral ligament of the knee-joint.

The **Semimembranosus** (Figs. 346 and 349), so called from its membranous tendon of origin, is situated at the back part and inner side of the thigh. It arises by a thick tendon from the upper and outer impression on the back part of the tuberosity of the ischium, above and to the outer side of the Biceps and Semitendinosus, and is inserted into the groove on the inner and back part of the inner tuberosity of the tibia, beneath the internal lateral ligament. The tendon of the muscle at its origin expands into an aponeurosis which covers the upper part.
of its anterior surface: from this aponeurosis muscular fibres arise, and converge to another aponeurosis, which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of the muscle at its insertion gives off certain fibrous expansions; one of these, of considerable size, passes upward and outward to be inserted into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint; a second is continued downward to the fascia which covers the Popliteus muscle. The tendon also sends a few fibres to join the internal lateral ligament of the joint.

The tendons of the two preceding muscles, with that of the Gracilis, form the inner hamstrings.

Relations.—By its superficial surface, with the Gluteus maximus, Semitendinosus, Biceps, and fascia lata; by its deep surface, with the origin of the Quadratus femoris, popliteal vessels, Adductor magnus, and inner head of the Gastrocnemius; by its inner border, with the Gracilis; by its outer border, with the great sciatic nerve, and its internal popliteal branch. There is a bursa between the Gastrocnemius and Semimembranosus and another bursa between the Semimembranosus and the inner condyle of the tibia. The first bursa usually communicates with the knee-joint. These two bursae are in communication and in reality constitute a double bursa (bursa m. semimembranos).

Nerves.—The muscles of this region are supplied by the first, second, and third sacral nerves through the great sciatic nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps, in consequence of its oblique direction downward and outward, rotates the leg slightly outward; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inward, assisting the Popliteus. Taking their fixed point from below, these muscles, especially the Semimembranosus, serve to support the pelvis upon the head of the femur and to draw the trunk directly backward, as in raising it from the stooping position or in feats of strength, when the body is thrown backward in the form of an arch. When the leg is extended on the thigh, they limit the amount of flexion of the trunk on the lower limbs.

Surgical Anatomy.—The hamstring tendons are occasionally ruptured. In disease of the knee-joint the hamstrings may contract, flexing the knee, drawing the tibia backward, and sometimes causing incomplete dislocation. The tendons of these muscles occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the Flexor muscles, or from stiffening of the ligamentous and other tissues surrounding the joint, the result of disease. Division of a tendon is effected by putting the tendon upon the stretch, and inserting a narrow sharp-pointed knife between it and the skin: the cutting edge being then turned toward the tendon, it should be divided, taking great care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve to the tendon of the Biceps must always be borne in mind in dividing this tendon.

III. MUSCLES AND FASCIAE OF THE LEG.

These may be divided into three groups: those on the anterior, those on the posterior, and those on the outer side of the leg.

5. The Anterior Tibio-fibular Region (Fig. 350).

Tibialis anticus. Extensor longus digitorum.

Extensor proprius hallucis. Peroneus tertius.

1 There is no such word as "Hallux,-cis." It is the result of some ignorant blunder, copied until it has become established by usage; it has been thought better, therefore, to retain it. According to Lewis and Short, the word is Alex, masculine; genitive, Alexis, the great toe, and the correct rendering would be Extensor proprius hallucis. It is a rare word, and is sometimes spelt, but not so correctly, "Hallex." It is used by Plautus, in the "Poenulus," V. v. 31, of a little man, as we might say "a hop-o'-my-thumb," "Tunc hic amatris audivit esse, aequo viril!" (To think of you daring to make up to her, you hop-o'-my-thumb). The word "alex," sometimes spelt "alex," a fish sauce, is probably a different word altogether. It is used by Horace and Pliny.

Dissection (Fig. 341).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

The Deep Fascia of the Leg (fascia cruris) forms a complete investment to the muscles, but is not continuous over the subcutaneous surfaces of the bones. It is continuous above with the fascia lata, receiving an expansion from the tendon of the Biceps on the outer side, and from the tendons of the Sartorius, Gracilis, and Semitendinosus on the inner side; in front it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; below it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles, but is thinner behind, where it covers the Gastrocnemius and Soleus muscles. Over the popliteal space it is much strengthened by transverse fibres which stretch across from the inner to the outer hamstring muscles, and it is here perforated by the external saphenous vein. Its deep surface gives off, on the outer side of the leg, two strong intermuscular septa which enclose the Peronei muscles, and separate them from the muscles of the anterior and posterior tibial regions. It also gives off several smaller and more slender processes which enclose the individual muscles in each region; at the same time a broad transverse intermuscular septum, called the deep transverse fascia of the leg, intervenes between the superficial and deep muscles in the posterior tibio-fibular region.

Remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left entire. Commence the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscular fibres.

The Tibialis Anticus (m. tibialis anterior) is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It arises from the outer tuberosity and upper two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum: the fibres pass vertically downward, and terminate in a tendon which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is inserted into the inner and under surface of the internal cuneiform bone and base of the metatarsal bone of the great toe. There is usually a bursa (bursa subtendinea m. tibialis anterioris) between the tendon of the tibialis anticus and the internal cuneiform bone.

Relations.—By its anterior surface, with the fascia and with the annular ligament; by its posterior surface, with the interosseous membrane, tibia, ankle-joint, and inner side of the tarsus: this surface also overlaps the anterior tibial vessels and nerve in the upper part of the leg. By its inner surface, with the tibia; by its outer surface, with the Extensor longus digitorum and Extensor proprius hallucis, and the anterior tibial vessels and nerve.

The Extensor Proprius Hallucis (m. extensor hallucis longus) is a thin, elongated, and flattened muscle situated between the Tibialis anticus and Extensor longus digitorum. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also arises from the interosseous membrane to a similar extent. The fibres pass downward, and terminate in a tendon which occupies
the anterior border of the muscle, passes through a distinct compartment in the lower portion of the annular ligament, crosses the anterior tibial vessels near the bend of the ankle, and is inserted into the base of the last phalanx of the great toe. Opposite the metatarsophalangeal articulation the tendon gives off a thin prolongation on each side, which covers the surface of the joint. It usually sends an expansion from the inner side of the tendon, to be inserted into the base of the first phalanx.

Relations.—By its anterior surface, with the fascia and the anterior annular ligament; by its posterior surface, with the interosseous membrane, fibula, tibia, and ankle-joint; by its outer side, with the Extensor longus digitorum above, the dorsalis pedis vessels, anterior tibial nerve, and Extensor brevis digitorum below; by its inner side, with the Tibialis anticus and the anterior tibial vessels above. The muscle is external to the anterior tibial vessels in the upper part of the leg; but in the lower third its tendon crosses over them, so that it lies internal to them on the dorsum of the foot.

The Extensor Longus Digitorum (m. extensor digitorum longus) is an elongated, flattened, penniform muscle situated the most externally of all the muscles on the forepart of the leg. It arises from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner and the Peronei on the outer side. The tendon enters a canal in the annular ligament with the Peroneus tertius, and divides into four slips, which run across the dorsum of the foot and are inserted into the second and third phalanges of the four lesser toes. The mode in which the tendons are inserted is the following: Each of the three inner tendons opposite the metatarsophalangeal articulation is joined, on its outer side, by a tendon from the Extensor brevis digitorum. The outer tendon does not receive such a tendinous slip. They all receive a fibrous expansion from the Interossei and Lumbricales, and then spread out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips—a middle one, which is inserted into the base of the second phalanx, and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onward, to be inserted into the base of the third.

Relations.—By its anterior surface, with the fascia and the annular ligament; by its posterior surface,
with the fibula, interosseous membrane, ankle-joint, and Extensor brevis digitorum; by its inner side, with the Tibialis anticus, Extensor proprius hallucis, and anterior tibial vessels and nerve; by its outer side, with the Peroneus longus and brevis.

The **Peroneus Tertius** (m. peroneus tertius) is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower fourth of the anterior surface of the fibula, from the lower part of the interosseous membrane, and from an intermuscular septum between it and the Peroneus brevis. The tendon, after passing through the same canal in the annular ligament as the Extensor longus digitorum, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe. This muscle is sometimes wanting.

**Nerves.**—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the anterior tibial nerve.

**Actions.**—The Tibialis anticus and Peroneus tertius are the direct flexors of the foot at the ankle-joint; the former muscle, when acting in conjunction with the Tibialis posticus, raises the inner border of the foot (i.e., inverts the foot); and the latter, acting with the Peroneus brevis and longus, draws the outer border of the foot upward and the sole outward (i.e., everts the foot). The Extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed point from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position, and give increased strength to the ankle-joint.

**6. The Posterior Tibio-fibular Region** (Figs. 349, 352).

**Dissection** (Fig. 345).—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal space to the heel, connecting it below by a transverse incision extending between the two malleoli; the flaps of integument being removed, the fascia and muscles should be examined.

The muscles in this region of the leg are subdivided into two layers—superficial and deep. The superficial layer constitutes a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct connection with his ordinary attitude and mode of progression.

**The Superficial Layer.**

**Gastrocnemius.**

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by two strong flat tendons. The inner and larger head (caput medialis) arises from a depression at the upper and back part of the inner condyle and from the adjacent part of the femur. There is a **bursa** (bursa m. gastrocnemii medialis) between the tendon of origin and the inner condyle. The outer head (caput laterale) arises from an impression on the outer side of the external condyle and from the posterior surface of the femur immediately above the condyle. There is a **bursa** (bursa m. gastrocnemii lateralis) between the tendon of origin and the outer condyle. Both heads, also, arise by a few tendinous and fleshy fibres from the ridges which are continued upward from the condyles to the linea aspera. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs; the muscular fibres of the inner head being thicker and extending lower than those of the outer. From the anterior surface of these tendinous expansions muscular fibres are given off.
The fibres in the median line, which correspond to the accessory portions of the muscle derived from the bifurcations of the linea aspera, unite at an angle upon a median tendinous raphe below: the remaining fibres converge to an aponeurosis which covers the anterior surface of the muscle, and this, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendon Achillis.

Relations.—By its superficial surface, with the fascia of the leg, which separates it from the external saphenous vein and nerve; by its deep surface, with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. The tendon of the inner head corresponds with the back part of the inner condyle, from which it is separated by a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head contains a sesamoid fibro-cartilage (rarely osseous) where it plays over the corresponding outer condyle; and one is occasionally found in the tendon of the inner head.

The Gastrocnemius should be divided across, just below its origin, and turned downward, in order to expose the next two muscles.

The Soleus is a broad flat muscle situated immediately beneath the Gastrocnemius. It has received its name from its resemblance in shape to a sole-fish. It arises by tendinous fibres from the back part of the head of the fibula and from the upper third of the posterior surface of its shaft; from the oblique line of the tibia and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the popliteal vessels and internal popliteal nerve pass. The fibres pass backward to an aponeurosis which covers the posterior surface of the muscle, and this, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendon Achillis.

The triceps surae is the designation in the new nomenclature of the Gastrocnemius and Soleus.

Relations.—By its superficial surface, with the Gastrocnemius and Plantaris; by its deep surface, with the Flexor longus digitorum, Flexor longus hallucis, Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The Tendo Achillis (tendo calcaneus), the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest tendon in the body. It is about six inches in length, and commences about the middle of the leg, but receives fleshy fibres on its anterior surface nearly to its lower end. Gradually becoming contracted below, it is inserted into the lower part of the posterior surface of the os calcis, a synovial bursa, the retro-calcaneal bursa (bursa tendinis calcanei [Achillis]) (Fig. 351), being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is usually about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, a bursa (bursa subcutanea calcanea) (Fig. 351) being often interposed between the tendon and the fascia. The tendon
is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its outer side, but superficial to it, is the external saphenous vein.

The **Plantaris** is an extremely diminutive muscle placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It **arises**
from the lower part of the outer prolongation of the linea aspera and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and, running along the inner border of the tendo Achillis, is inserted with it into the posterior part of the os calcis. This muscle is occasionally double, and is sometimes wanting. Occasionally its tendon is lost in the internal annular ligament or in the fascia of the leg.

Nerves.—The Gastrocnemius is supplied by the first and second sacral nerves, and the Plantaris by the fourth and fifth lumbar and first sacral nerves through the internal popliteal. The Soleus is supplied by the fifth lumbar and first and second sacral nerves through the internal popliteal and posterior tibial.

Actions.—The muscles of the calf are the chief extensors of the foot at the ankle-joint. They possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking these muscles draw powerfully upon the os calcis, raising the heel, and with it the entire body, from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forward. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot, and prevents the body from falling forward, to which there is a constant tendency from the superincumbent weight. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia, assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which exists in some of the lower animals and is continued over the os calcis to be inserted into the plantar fascia. In man it is an accessory to the Gastrocnemius, extending the ankle if the foot is free, or bending the knee if the foot is fixed. Possibly, acting from below, by its attachment to the posterior ligament of the knee-joint, it may pull that ligament backward during flexion, and so protect it from being compressed between the two articular surfaces.

The Deep Layer (Fig. 353).

- Popliteus.
- Flexor longus hallucis.
- Flexor longus digitorum.
- Tibialis posticus.

Dissection.—Detach the Soleus from its attachment to the fibula and tibia, and turn it downward, when the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

Deep Transverse Fascia.—The deep transverse fascia of the leg is a transversely placed, intermuscular septum, between the superficial and deep muscles in the posterior tibio-fibular region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the leg, but below, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the internal annular ligament.

This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The Popliteus (Fig. 349) is a thin, flat, triangular muscle, which forms part of the floor of the popliteal space. It arises by a strong tendon, about an inch in length, from a deep depression on the outer side of the external condyle of the femur, and from the posterior ligament of the knee-joint. A bursa (bursa m. poplitei) is placed between the condyle and the muscle. The muscle is inserted into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle. The tendon of the muscle is covered by that of the Biceps and by the external lateral ligament of the knee-joint; it grooves
the posterior border of the external semilunar fibro-cartilage, and is invested by the synovial membrane of the knee-joint.

**Relations.**—By its superficial surface, with the fascia covering it, which separates it from the Gastrocnemius, Plantaris, popliteal vessels, and internal popliteal nerve; by its deep surface, with the knee-joint and back of the tibia.

The **Flexor Longus Hallucis** (*m. flexor hallucis longus*) is situated on the fibular side of the leg, and is the most superficial and largest of the three next muscles. It arises from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the Peronei, externally; and from the fascia covering the Tibialis posticus internally. The fibres pass obliquely downward and backward, and terminate in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon occupies a groove on the posterior surface of the lower end of the tibia; it then lies in a second groove on the posterior surface of the astragalus, and finally in a third groove, beneath the sustentaculum tali of the os calcis, and passes into the sole of the foot, where it runs forward between the two heads of the Flexor brevis hallucis, and is inserted into the base of the last phalanx of the great toe (Fig. 355). The grooves in the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals lined by synovial membrane; and as the tendon crosses the sole of the foot, it is connected to the common flexor by a tendinous slip.

**Relations.**—By its superficial surface, with the Soleus and tendon Achillis, from which it is separated by the deep transverse fascia; by its deep surface, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; by its outer border, with the Peronei; by its inner border, with the Tibialis posticus and posterior tibial vessels and nerve. In the sole of the foot it lies above the Abductor hallucis and Flexor longus digitorum.

The **Flexor Longus Digitorum** (*m. flexor digitorum longus*) is situated on the tibial side of the leg. At its origin it is thin and pointed, but gradually increases in size as it descends. It arises from the posterior surface of the shaft of the tibia, immediately below the oblique line to within three inches of its extremity, internal to the tibial origin of the Tibialis posticus; some fibres also arise from the fascia covering the Tibialis posticus. The fibres terminate in a tendon which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the internal malleolus in a groove, common to it and the Tibialis posticus, but separated from the latter by a fibrous septum, each tendon being contained in a special sheath lined by a separate synovial membrane. It then passes obliquely forward and outward, superficial to the internal lateral ligament, into the sole of the foot (Fig. 355), where, crossing superficial to the tendon of the Flexor longus hallucis, to which it is connected by a strong tendinous slip, it becomes expanded, is joined by the Flexor accessorius, and finally divides into four tendons which are inserted into the bases of the last phalanges of the four lesser toes, each tendon passing through a fissure in the tendon of the Flexor brevis digitorum opposite the base of the first phalanges (Fig. 354).

**Relations.**—In the leg: by its superficial surface, with the posterior tibial vessels and nerve, and the deep transverse fascia, which separates it from the Soleus muscle; by its deep surface, with the Tibia and Tibialis posticus. In the foot it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The **Tibialis Posticus** (*m. tibialis posterior*) lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It com-

---

1 That is, in the order of dissection of the sole of the foot.
mences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forward to the front of the leg. It *arises* from the whole of the posterior surface of the interosseous membrane, excepting its lowest part, from the outer portion of the posterior surface of the shaft of the tibia, between the commencement of the oblique line above, and the junction of the middle and lower third of the shaft below; and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia and from the intermuscular septa, separating it from the adjacent muscles on each side. This muscle, in the lower fourth of the leg, passes in front of the Flexor longus digitorum, and terminates in a tendon which passes through a groove behind the inner malleolus with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneo-scaphoid ligament, and is *inserted* into the tuberosity of the scaphoid and internal cuneiform bones (Fig. 356). The tendon of this muscle contains a sesamoid fibro-cartilage as it passes over the scaphoid bone, and gives off fibrous expansions, one of which passes backward to the sustentaculum tali of the os calcis, others outward to the middle and external cuneiform and cuboid, and some forward to the base of the second, third, and fourth metatarsal bones (Fig. 355).

**Relations.**—By its *superficial surface*, with the Soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels; by its *deep surface*, with the interosseous ligament, the tibia, fibula, and ankle-joint.

**Nerves.**—The Popliteus is supplied by the fourth and fifth lumbar and first sacral nerves, through the internal popliteal; the Flexor longus digitorum and Tibialis posterior by the fifth lumbar and first sacral; and the Flexor longus hallucis by the fifth lumbar and first and second sacral nerves through the posterior tibial.

**Actions.**—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inward. It is especially called into action at the commencement of the act of bending the knee, inasmuch as it produces a slight inward rotation of the tibia, which is essential in the early stage of this movement. The Tibialis posterior is a direct extensor of the foot at the ankle-joint; acting in conjunction with the Tibialis anticus, it turns the sole of the foot inward (*i.e.*, inverts the foot), antagonizing the Peronei, which turn it outward (evert it). In the sole of the foot the tendon of the Tibialis posterior lies directly below the inferior calcaneo-scaphoid ligament, and is therefore an important factor in maintaining the arch of the foot. The Flexor longus digitorum and Flexor longus hallucis are the direct flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking or in standing on tip toe. In consequence of the oblique direction of the tendon of the long flexor the toes would be drawn inward were it not for the Flexor accessorius muscle, which is inserted into the outer side of its tendon and draws it to the middle line of the foot during its action. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly upon the ankle-joint. They also serve to raise these bones from the oblique position they assume in the stooping posture.

7. **The Fibular Region** (Fig. 353).

Peroneus longus. Peroneus brevis.

**Dissection.**—The muscles are readily exposed by removing the fascia covering their surface, from below upward, in the line of direction of their fibres.

The **Peroneus Longus** (*m. peroneus longus*) is situated at the upper part of the outer side of the leg, and is the more superficial of the two muscles. It *arises*
from the head and upper two-thirds of the outer surface of the shaft of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the front, and those on the back of the leg, occasionally also by a few fibres from the outer tuberosity of the tibia. Between its attachment to the head and to the shaft of the fibula there is a small interval of bone from which no muscular fibres arise; through this gap the external popliteal nerve passes beneath the muscle. The muscle terminates in a long tendon, which passes behind the outer malleolus, in a groove common to it and the tendon of the Peroneus brevis, behind which it lies, the groove being converted into a canal by a fibrous band, and the tendons being invested by a common synovial membrane; it is then reflected obliquely forward across the outer side of the os calcis, below its peroneal tubercle, being contained in a separate fibrous sheath, lined by a prolongation of the synovial membrane which lines the groove behind the malleolus. Having reached the outer side of the cuboid bone, it runs in a groove on the under surface of that bone, which is converted into a canal by the long calcaneocuboid ligament, and is lined by a synovial membrane: the tendon then crosses the sole of the foot obliquely, and is inserted into the outer side of the base of the metatarsal bone of the great toe and the internal cuneiform bone (Figs. 355 and 356). Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points: first, behind the external malleolus; secondly, on the outer side of the cuboid bone; in both of these situations the tendon is thickened, and in the latter a sesamoid fibro-cartilage, or sometimes a bone, is usually developed in its substance.

Relations.—By its superficial surface, with the fascia and integument; by its deep surface, with the fibula, external popliteal nerve, the Peroneus brevis, os calcis, and cuboid bone; by its anterior border, with an intermuscular septum, which intervenes between it and the Extensor longus digitorum; by its posterior border, with an intermuscular septum, which separates it from the Soleus above and the Flexor longus hallucis below.

The Peroneus Brevis (m. peroneus brevis) lies beneath the Peroneus longus, and is shorter and smaller than it. It arises from the lower two-thirds of the external surface of the shaft of the fibula, internal to the Peroneus longus, and from the intermuscular septa separating it from the adjacent muscles on the front and back part of the leg. The fibres pass vertically downward, and terminate in a tendon which runs in front of that of the preceding muscle through the same groove, behind the external malleolus, being contained in the same fibrous sheath and lubricated by the same synovial membrane. It then passes through a separate sheath on the outer side of the os calcis, above that for the tendon of the Peroneus longus, the two tendons being here separated by the peroneal tubercle, and is finally inserted into the tuberosity at the base of the metatarsal bone of the little toe, on its outer side.

Relations.—By its superficial surface, with the Peroneus longus and the fascia of the leg and foot; by its deep surface, with the fibula and outer side of the os calcis.

Nerves.—The Peroneus longus and brevis are supplied by the fourth and fifth lumbar and first sacral nerves through the musculo-cutaneous branch of the external popliteal nerve.

Actions.—The Peroneus longus and brevis extend the foot upon the leg, in conjunction with the Tibialis posticus, antagonizing the Tibialis anticus and Peroneus tertius, which are flexors of the foot. The Peroneus longus also everts the sole of the foot; hence the extreme eversion occasionally observed in fracture of the lower end of the fibula, where that bone offers no resistance to the action of this muscle. From the oblique direction of the Peroneus longus tendon across the sole of the foot it is an important agent in the maintenance of the transverse
arch of the foot. Taking their fixed point below, the Peronei serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the tendency of the superincumbent weight is to throw the leg inward: the Peroneus longus overcomes this tendency by drawing on the outer side of the leg, and thus maintains the perpendicular direction of the limb.

**Surgical Anatomy.**—The student should now consider the position of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding blood-vessels, and especially their action upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as club-foot. The most simple and common deformity, and one that is rarely, if ever, congenital, is the talipes equinus, the heel being raised by rigidity and contraction of the Gastrocnemius muscle, and the patient walking upon the ball of the foot. In the talipes varus the foot is forcibly adducted and the inner side of the sole raised, sometimes to a right angle with the ground, by the action of the Tibialis anticus and posticus. In the talipes valgus the outer edge of the foot is raised by the Peronei muscles, and the patient walks on the inner ankle. In the talipes calcaneus the toes are raised by the Extensor muscles, the heel is depressed, and the patient walks upon it. Other varieties of deformity are met with, as the talipes equino-varus, equino-valgus, and calcaneo-valgus, whose names sufficiently indicate their nature. Of these, the talipes equino-varus is the most common congenital form: the heel is raised by the tendo Achillis, the inner border of the foot drawn upward by the Tibialis anticus, the anterior two-thirds twisted inward by the Tibialis posterior, and the arch increased by the contraction of the plantar fascia; so that the patient walks on the middle of the outer border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia; by this means the foot regains its proper position, and the tendons subsequently heal. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it. Pes cavus or hollow foot is accentuation of the longitudinal arch. Pes planus or flat-foot has been discussed elsewhere.

**Rupture** of a few of the fibres of the Gastrocnemius may take place. Rupture of the Plantaris tendon not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn tennis, and is hence known as lawn-tennis leg. The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo Achillis is also sometimes ruptured. It is stated that John Hunter ruptured his tendo Achillis whilst dancing at the age of forty. The retro-calcaneal bursa is interposed between the posterior surface of the os calcis and the tendo Achillis, just above the point of insertion of the tendon. If it inflames it produces disabling pain (achillodynia, or Albert's disease, retro-calcaneal bursitis). This bursa may become cartilaginous or osteophytes may form on the surface toward the os calcis.

**IV. MUSCLES AND FASCIA OF THE FOOT.**

The fibrous bands, or thickened portions of the fascia of the leg, which bind down the tendons in front of and behind the ankle in their passage to the foot should now be examined; they are termed the annular ligaments, and are three in number—anterior, internal, and external.

The Anterior Annular Ligament (Fig. 350) consists of a superior or transverse portion (ligamentum transversum cruris) which binds down the Extensor tendons as they descend on the front of the tibia and fibula; and an inferior or Y-shaped portion (ligamentum cruciatum cruris), which retains them in connection with the tarsus, the two portions being connected by a thin intervening layer of fascia. The transverse portion is attached externally to the lower end of the fibula and internally to the tibia; above it is continuous with the fascia of the leg; it contains only one synovial sheath, for the tendon of the Tibialis anticus; the other tendons and the anterior tibial vessels and nerve passing beneath it, but without any distinct synovial sheath. The Y-shaped portion is placed in front of the ankle-joint, the stem of the Y, the fundiform ligament of Retzius, being attached externally to the upper surface of the os calcis, in front of the depression for the interosseous ligament; it is directed inward, as a double layer, one lamina passing in front, and the other behind, the tendons of the Peroneus tertius and Extensor longus digitorum. At the inner border of the latter tendon these two layers join together,
forming a sort of loop or sheath in which the tendons are enclosed, surrounded by a synovial membrane. From the inner extremity of this loop the two limbs of the Y diverge: one passes upward and inward, to be attached to the internal malleolus, passing over the Extensor proprius hallucis and the vessels and nerves, but enclosing the Tibialis anticus and its synovial sheath by a splitting of its fibres. The other limb extends downward and inward to be attached to the inner border of the plantar fascia, and passes over the tendons of the Extensor proprius hallucis and Tibialis anticus and also the vessels and nerves. These two tendons are contained in separate synovial sheaths situated beneath the ligament.

The Internal Annular Ligament (ligamentum laeiniatitum) is a strong fibrous band which extends from the inner malleolus above to the internal margin of the os calcis below, converting a series of grooves in this situation into canals for the passage of the tendons of the Flexor muscles and vessels into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar fascia and the fibres of origin of the Abductor hallucis muscle. The four canals which it forms transmit, counting from before backward, first, the tendon of the Tibialis posticus; second, the tendon of the Flexor longus digitorum; third, the posterior tibial vessels and nerve, which run through a broad space beneath the ligament; lastly, in a canal formed partly by the astragalus, the tendon of the Flexor longus hallucis. The canals for the tendons are lined by a separate synovial membrane.

The External Annular Ligament is divided into two portions; a superior portion (retinaculum mm. peronarorum superius), which extends from the extremity of the outer malleolus to the outer surface of the os calcis: it binds down the tendons of the Peroneus longus and brevis muscles in their passage behind the external malleolus. The two tendons are enclosed in one synovial sac. An inferior portion (retinaculum mm. peronarorum inferius), which bridges the Peronei on the side of the os calcis and is attached to the bone above and below them.

Dissection of the Sole of the Foot.—The foot should be placed on a high block with the sole uppermost, and firmly secured in that position. Carry an incision round the heel and along the inner and outer borders of the foot to the great and little toes. This incision should divide the integument and thick layer of granular fat beneath until the fascia is visible; the skin and fat should then be removed from the fascia in a direction from behind forward, as seen in Fig. 345.

Plantar Fascia (aponeurosis plantaris).—The plantar fascia, the densest of all the fibrous membranes, is of great strength, and consists of pearly-white glistening fibres, disposed, for the most part, longitudinally: it is divided into a central and two lateral portions.

Central Portion.—The central portion, the thickest, is narrow behind and attached to the inner tubercle of the os calcis, posterior to the origin of the Flexor brevis digitorum, and, becoming broader and thinner in front, divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes divides opposite the metatarso-phalangeal articulation into two strata, superficial and deep. The superficial stratum is inserted into the skin of the transverse sulcus which divides the toes from the sole. The deeper stratum divides into two slips which embrace the sides of the flexor tendons of the toes, and blend with the sheaths of the tendons, and laterally with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long flexors pass to the toes. The intervals left between the five processes allow the digital vessels and nerves and the tendons of the Lumbricales muscles to become superficial. At the point of division of the fascia into processes and slips numerous transverse fibres are superadded, which serve to increase the strength of the fascia at this part by binding the processes
together and connecting them with the integument. The central portion of the plantar fascia is continuous with the lateral portions at each side, and sends upward into the foot, at their point of junction, two strong vertical intermuscular septa, broader in front than behind, which separate the middle from the external and internal plantar group of muscles; from these, again, thinner transverse septa are derived, which separate the various layers of muscles in this region. The upper surface of this fascia gives attachment behind to the Flexor brevis digitorum muscle.

**Lateral Portions.**—The lateral portions of the plantar fascia are thinner than the central piece, and cover the sides of the foot. The outer portion covers the under surface of the Abductor minimi digitii; it is thick behind, thin in front, and extends from the os calcis, forward, to the base of the fifth metatarsal bone, into the outer side of which it is attached; it is continuous internally with the middle portion of the plantar fascia, and externally with the dorsal fascia. The inner portion is very thin, and covers the Abductor hallucis muscle; it is attached behind to the internal annular ligament, and is continuous around the side of the foot with the dorsal fascia, and externally with the middle portion of the plantar fascia.

**Bursae about the Ankle and Foot.**—(1) A subcutaneous bursa on the sole of the foot, beneath the tuberosity of the os calcis. (2) A subcutaneous bursa over the tendo Achillis (bursa subcutanea calcanea). (3) The retrocalcaneal bursa, between the posterior surface of the os calcis and the insertion of the tendo Achillis (bursa tendinis calcanei [Achillis]). (4) A bursa between the internal cuneiform bone and the tendon of the Tibialis anticus (bursa subtendinea m. tibialis anteriors). (5) Bursae between the heads of the metatarsal bones (bursae intermetatarsophalangeae). (6) A subcutaneous bursa over the internal malleolus (bursa subcutanea malleoli medialis). (7) Bursae between the scaphoid and middle cuneiform bones on the one hand and the tendon of the Tibialis posterior on the other (bursa subtendinea m. tibialis posterioris). (8) Bursae between the Lumbricales and the transverse ligaments (bursae mm. lumbricalium pedis). (9) A bursa over the external malleolus (bursa subcutanea malleoli lateralis). (10) A bursa over the head of the first metatarsal bone. Various muscles have tendon-sheaths lined with synovial membrane (vaginal sheaths).

**Surgical Anatomy.**—The dense plantar fascia aids powerfully in maintaining the arch of the foot. When this fascia stretches or gives way flat-foot forms. In some forms of club-foot the plantar fascia is contracted. This contraction is usually a secondary change.

When inflammation causes tenderness and enlargement of the bursa over the metatarsophalangeal articulation of the great toe, the enlargement is called a bunion. Enlargement of the retro-calcaneal bursa is known as Albert's disease, or achillodynia.

8. The Dorsal Region (Fig. 350).

Extensor brevis digitorum.

**Fascia** (fascia dorsalis pedis).—The fascia on the dorsum of the foot is a thin membranous layer continuous above with the anterior margin of the annular ligament; it becomes gradually lost opposite the heads of the metatarsal bones, and on each side blends with the lateral portions of the plantar fascia; it forms a sheath for the tendons placed on the dorsum of the foot. On the removal of this fascia the muscles and tendons of the dorsal region of the foot are exposed.

The **Extensor Brevis Digitorum** (m. extensor digitorum brevis) (Fig. 350) is a broad thin muscle which arises from the forepart of the upper and outer surfaces of the os calcis, in front of the groove for the Peroneus brevis, from the external calcaneo-astragaloid ligament, and from the common limb of the Y-shaped portion of the anterior annular ligament. It passes obliquely
across the dorsum of the foot, and terminates in four tendons. The innermost, which is the largest, is inserted into the dorsal surface of the base of the first phalanx of the great toe, crossing the dorsalis pedis artery; the other three, into the outer sides of the long extensor tendons of the second, third, and fourth toes.

**Relations.**—By its superficial surface, with the fascia of the foot, the tendons of the Extensor longus digitorum and Peroneus tertius; by its deep surface, with the tarsal and metatarsal arteries and bones and the Dorsal interossei muscles.

**Nerves.**—It is supplied by the anterior tibial nerve.

**Actions.**—The Extensor brevis digitorum is an accessory to the long Extensor, extending the phalanges of the four inner toes, but acting only on the first phalanx of the great toe. The obliquity of its direction counteracts the oblique movement given to the toes by the long Extensor, so that, both muscles acting together, the toes are evenly extended.

The muscles in the plantar region of the foot may be divided into three groups, in a similar manner to those in the hand. Those of the internal plantar region are connected with the great toe, and correspond with those of the thumb; those of the external plantar region are connected with the little toe, and correspond with those of the little finger; and those of the middle plantar region are connected with the tendons intervening between the two former groups. But in order to facilitate the dissection of these muscles it will be found more convenient to divide them into four layers, as they present themselves, in the order in which they are successively exposed.

**The First Layer.**

Abductor hallucis.  
Flexor brevis digitorum.  
Abductor minimi digiti.

**Dissection.**—Remove the fascia on the inner and outer sides of the foot, commencing in front over the tendons and proceeding backward. The central portion should be divided transversely in the middle of the foot, and the two flaps dissected forward and backward.

The **Abductor Hallucis** lies along the inner border of the foot. It arises from the inner tubercle on the under surface of the os calcis; from the internal annular ligament; from the plantar fascia; and from the intermuscular septum between it and the Flexor brevis digitorum. The fibres terminate in a tendon which is inserted, together with the innermost tendon of the Flexor brevis hallucis, into the inner side of the base of the first phalanx of the great toe.

**Relations.**—By its superficial surface, with the plantar fascia; by its deep surface, with the Flexor brevis hallucis, the Flexor accessorius, and the tendons of the Flexor longus digitorum and Flexor longus hallucis, the Tibialis anticus and posticus, the plantar vessels and nerves. Its outer border is in relation to the Flexor brevis digitorum.

The **Flexor Brevis Digitorum** (m. flexor digitorum brevis) lies in the middle of the sole of the foot, immediately beneath\(^1\) the plantar fascia, with which it is firmly united. It arises by a narrow tendinous process, from the inner tubercle of the os calcis, from the central part of the plantar fascia, and from the intermuscular septa between it and the adjacent muscles. It passes forward, and divides into four tendons, one for each of the four outer toes. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor longus digitorum:

\(^1\) That is, in order of dissection of the sole of the foot.
the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long flexor tendon. Finally, they divide a second time, to be inserted into the sides of the second phalanges about their middle. The mode of division of the tendons of the Flexor brevis digitorum and their insertion into the phalanges is analogous to the division and insertion of the Flexor sublimis digitorum in the hand.

Relations.—By its superficial surface, with the plantar fascia; by its deep surface, with the Flexor accessorius, the Lumbricales, the tendons of the Flexor longus digitorum, and the external plantar vessels and nerve, from which it is separated by a thin layer of fascia. The outer and inner borders are separated from the adjacent muscles by means of vertical prolongations of the plantar fascia.

Fibrous Sheaths of the Flexor Tendons.—These are not so well marked as in the fingers. The flexor tendons of the toes as they run along the phalanges are retained against the bones by a fibrous sheath, forming osseo-aponeurotic canals. These sheaths are formed by strong fibrous bands which arch across the tendons and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely, but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane which is reflected on the contained tendon.

The Abductor Minimi Digiti (m. abductor digitii quinti) lies along the outer border of the foot. It arises, by a very broad origin, from the outer tubercle of the os calcis, from the under surface of the os calcis between the two tubercles, from the forepart of the inner tubercle, from the plantar fascia and the intermuscular septum, between it and the Flexor brevis digitorum. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is inserted with the short Flexor of the little toe into the outer side of the base of the first phalanx of this toe.

Relations.—By its superficial surface, with the plantar fascia; by its deep surface, with the Flexor accessorius, the Flexor brevis minimi digitii, the long plantar ligament, and the tendon of the Peroneus longus. On its inner side are the external plantar vessels and nerve, and it is separated from the Flexor brevis digitorum by a vertical septum of fascia.

Dissection.—The muscles of the superficial layer should be divided at their origin by inserting the knife beneath each, and cutting obliquely backward, so as to detach them from the bone; they should then be drawn forward, in order to expose the second layer, but not cut away at their insertion. The two layers are separated by a thin membrane, the deep plantar fascia,
on the removal of which is seen the tendon of the Flexor longus digitorum, the Flexor accessorius, the tendon of the Flexor longus hallucis, and the Lumbricales. The long flexor tendons diverge from each other at an acute angle; the Flexor longus hallucis runs along the inner side of the foot, on a plane superior to that of the Flexor longus digitorum, the direction of which is obliquely outward.

The Second Layer.

Flexor accessorius. 

The Flexor Accessorius (*m. quadratus plantae*) arises by two heads, which are separated from each other by the long plantar ligament: the inner or larger head, which is muscular, being attached to the inner concave surface of the os calcis below the groove which lodges the tendon of the Flexor longus digitorum; the outer head, flat and tendinous, to the outer surface of the os calcis, in front of its lesser tubercle, and to the long plantar ligament; the two portions join at an acute angle, and are inserted into the outer margin and upper and under surfaces of the tendon of the Flexor longus digitorum, forming a kind of groove in which the tendon is lodged.¹

Relations.—By its superficial surface, with the muscles of the superficial layer, from which it is separated by the external plantar vessels and nerves; by its deep surface, with the os calcis and long calcaneo-cuboid ligament.

The Lumbricales are four small muscles accessory to the tendons of the Flexor longus digitorum: they arise from the tendons of the long Flexor, as far back as their angle of division, each arising from two tendons, except the internal one. Each muscle terminates in a tendon, which passes forward on the inner side of the four lesser toes and is inserted into the expansion of the long Extensor tendon on the dorsum of the first phalanx of the corresponding toe.

Dissection.—The flexor tendons should be divided at the back part of the foot, and the Flexor accessorius at its origin, and drawn forward, in order to expose the third layer.

The Third Layer.

Flexor brevis hallucis. Flexor brevis minimi digitii.

Adductor obliquus hallucis. Adductor transversus hallucis.

The Flexor Brevis Hallucis (*m. flexor hallucis brevis*) arises, by a pointed tendinous process, from the inner part of the under surface of the cuboid bone, from the contiguous portion of the external cuneiform, and from the prolongation of the tendon of the Tibialis posticus, which is attached to that bone. The muscle divides, in front, into two portions, which are inserted into the inner and outer sides of the base of the first phalanx of the great toe, a sesamoid bone being developed in each tendon at its insertion. The inner portion of this muscle is blended with the Abductor hallucis previous to its insertion, the outer portion with the Adductor obliquus hallucis, and the tendon of the Flexor longus hallucis lies in a groove between them.

Relations.—By its superficial surface, with the Abductor hallucis and the tendon of the Flexor longus hallucis; by its deep surface, with the tendon of the Peroneus longus and metatarsal bone of the great toe; by its inner border, with the Abductor hallucis; by its outer border, with the Adductor obliquus hallucis.

The Adductor Obliquus Hallucis is a large, thick, fleshy mass passing obliquely across the foot and occupying the hollow space between the four inner metatarsal bones. It arises from the tarsal extremities of the second, third, and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus,

¹ According to Turner, the fibres of the Flexor accessorius end in aponeurotic bands, which contribute slips to the second, third, and fourth digits.
The Flexor Brevis Minimi Digiti (m. flexor digiti quinti brevis) lies on the metatarsal bone of the little toe, and much resembles one of the Interossei. It arises from the base of the metatarsal bone of the little toe, and from the sheath of the Peroneus longus; its tendon is inserted into the base of the first phalanx of the little toe on its outer side. Occasionally some of the deeper fibres of the muscle are inserted into the outer part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the Opponens minimi digiti.

**Relations.**—By its superficial surface, with the plantar fascia and tendon of the Abductor minimi digiti; by its deep surface, with the fifth metatarsal bone.
The Adductor Transversus Hallucis (*m. transversus pedis*) is a narrow, flat, muscular fasciculus, stretched transversely across the heads of the metatarsal bones, between them and the flexor tendons. It *arises* from the inferior metatarso-phalangeal ligaments of the three outer toes, sometimes only from the third and fourth and from the transverse ligament of the metatarsus; and is inserted into the outer side of the first phalanx of the great toe, its fibres being blended with the tendon of insertion of the Adductor obliquus hallucis.

**Relations.**—By its *superficial surface*, with the tendons of the long and short Flexors and Lumbricales; by its *deep surface*, with the Interossei.

**The Fourth Layer.**

**The Interossei.**

The Interossei Muscles in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the second toe, instead of the middle line of the third finger, as in the hand. They are seven in number, and consist of two groups, Dorsal and Plantar.

---

The Dorsal Interossei (*m. interossei dorsales*), four in number, are situated between the metatarsal bones. They are bipenniform muscles, *arising* by two heads from the adjacent sides of the metatarsal bones, between which they are placed; their tendons are *inserted* into the bases of the first phalanges, and into the aponeurosis of the common extensor tendon. In the angular interval left between the heads of each muscle at its posterior extremity the perforating arteries pass to the dorsum of the foot, except in the First interosseous muscle, where the interval allows the passage of the communicating branch of the dorsalis pedis artery. The First dorsal interosseous muscle is inserted into the inner side of the second toe; the other three are inserted into the outer sides of the second, third, and fourth toes.

The Plantar Interossei (*m. interossei plantares*), three in number, lie beneath, rather than between, the metatarsal bones. They are single muscles, and are each connected with but one metatarsal bone. They *arise* from the base and

---

Fig. 357.—The Dorsal interossei. Left foot. Fig. 358.—The Plantar interossei. Left foot.
inner sides of the shaft of the third, fourth, and fifth metatarsal bones, and are inserted into the inner sides of the bases of the first phalanges of the same toes, and into the aponeurosis of the common extensor tendon.

**Nerves.**—The Flexor brevis digitorum, the Flexor brevis and Abductor hallucis, and the innermost Lumbrical1 are supplied by the internal plantar nerve. All the other muscles in the sole of the foot by the external plantar. The first dorsal interosseous muscle, frequently receives an extra filament from the internal branch of the anterior tibial nerve on the dorsum of the foot, and the second dorsal interosseous a twig from the external branch of the same nerve.

**Actions.**—All the muscles of the foot act upon the toes, and for purposes of description as regard their action may be grouped as Abductors, Adductors, Flexors, or Extensors. The Abductors are the Dorsal interossei, the Abductor hallucis, and the Abductor minimi digitii. The Dorsal interossei are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe inward, toward the great toe; the second muscle draws the same toe outward; the third draws the third toe, and the fourth draws the fourth toe, in the same direction. Like the interossei in the hand, they also flex the proximal phalanges and extend the two terminal phalanges. The Abductor hallucis abducts the great toe from the others, and also flexes the proximal phalanx of this toe. And in the same way the action of the Abductor minimi digitii is twofold—as an abductor of this toe from the others, and also as a flexor of the proximal phalanx. The Adductors are the Plantar interossei, the Adductor obliquus hallucis, and the Adductor transversus hallucis. The Plantar interosseous muscles adduct the third, fourth, and fifth toes toward the imaginary line passing through the second toe, and by means of their insertion into the aponeurosis of the extensor tendon they, with the dorsal interossei, flex the proximal phalanges and extend the two terminal phalanges. The Adductor obliquus hallucis is chiefly concerned in adducting the great toe toward the second one, but also assists in flexing this toe. The Adductor transversus hallucis approximates all the toes, and thus increases the curve of the transverse arch of the metatarsus. The Flexors are the Flexor brevis digitorum, the Flexor accessorius, the Flexor brevis hallucis, the Flexor brevis minimi digitii, and the Lumbricales. The Flexor brevis digitorum flexes the second phalanges upon the first, and, continuing its action, may flex the first phalanges also and bring the toes together. The Flexor accessorius assists the Long flexor of the toes, and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor brevis hallucis flexes and slightly adducts the first phalanx of the great toe. The Flexor brevis minimi digitii flexes the little toe and draws its metatarsal bone downward and inward. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanx, and by their insertion into the long Extensor tendon aid in straightening the two terminal phalanges. The only muscle in the Extensor group is the Extensor brevis digitorum. It extends the first phalanx of the great toe, and assists the long Extensor in extending the next three toes, and at the same time gives to the toes an outward direction when they are extended.

**Surface Form of the Lower Extremity.**

Of the muscles of the thigh, those of the iliac region have no influence on surface form, while those of the anterior femoral region, being to a great extent superficial, largely contribute to the surface form of this part of the body. The Tensor fasciae femoris pro-

---

1 Formerly the two inner Lumbricales were described as being supplied by the internal plantar nerve. Brooks (Journal of Anatomy, vol. xxi, p. 575) in ten dissections found that in nine of them only the inner Lumbrical obtained its nerve supply from this source. In the tenth instance the first and second Lumbricales were supplied by both external and internal plantar.
duce a broad elevation immediately below the anterior portion of the crest of the ilium and behind the anterior superior spineous process. From its lower border a longitudinal groove, corresponding to the ilio-tibial band, may be seen running down the outer side of the thigh to the outer side of the knee-joint. The **Sartorius** muscle, when it is brought into action by flexing the leg on the thigh and the thigh on the pelvis, and rotating the thigh outward, presents a well-marked surface form. At its upper part, where it constitutes the outer boundary of Scarpa's triangle, it forms a prominent oblique ridge, which becomes changed into a flattened plane below, and this gradually merges in a general fullness on the inner side of the knee-joint. When the Sartorius is not in action, a depression exists between the **Quadriceps extensor** and the Adductor muscles, running obliquely downward and inward from the apex of Scarpa's triangle to the inner side of the knee, which depression corresponds to this muscle. In the depressed angle formed by the divergence of the Sartorius and Tensor fasciae femoris muscles, just below the anterior superior spineous process of the ilium, the **Rectus femoris** muscle appears, and, below this, determines to a great extent the convex form of the front of the thigh. In a well-developed subject the borders of the muscle, when in action, are clearly to be defined. The **Vastus externus** forms a long flattened plane on the outer side of the thigh, traversed by the longitudinal groove formed by the ilio-tibial band. The **Vastus internus**, on the inner side of the lower half of the thigh, gives rise to a considerable prominence, which increases toward the knee and terminates somewhat abruptly in this situation with a full, curved outline. The **Crureus und Subcrureus** are completely hidden, and do not directly influence surface form. The Adductor muscles, constituting the internal femoral group, are not to be individually distinguished from each other, with the exception of the upper tendon of the Adductor longus and the lower tendon of the Adductor magnus. The upper tendon of the **Adductor longus**, when the muscle is in action, stands out as a prominent ridge, which runs obliquely downward and outward from the neighborhood of the pubic spine, and forms the inner boundary of a flattened triangular space on the upper part of the front of the thigh, known as Scarpa's triangle. The lower tendon of the **Adductor magnus** can be distinctly felt as a short ridge extending down to the Adductor tubercle on the internal condyle, between the Sartorius and Vastus internus. The Adductor group of muscles fills in the triangular space at the upper part of the thigh, formed between the oblique femur and the pelvic wall, and to them is due the contour of the inner border of the thigh, the **Gracilis** largely contributing to the smoothness of the outline. These muscles are not marked off on the surface from those of the posterior femoral region by any intermuscular marking; but on the outer side of the thigh these latter muscles are defined from the Vastus externus by a distinct marking, corresponding to the external intermuscular septum. The **Gluteus maximus** and a part of the **Gluteus medius** are the only muscles of the buttock which influence surface form. The other part of the Gluteus medius, the Gluteus minimus, and the External rotators are completely hidden. The Gluteus maximus forms the full rounded outline of the buttock; it is more prominent behind, compressed in front, and terminates at its tendinous insertion in a depression immediately behind the great trochanter. Its lower border does not correspond to the gluteal fold, but is much more oblique, being marked by a line drawn from the side of the coccyx to the junction of the upper with the lower two-thirds of the thigh on the outer side. From beneath the lower margin of this muscle the Hamstring muscles appear, at first narrow and not well marked, but as they descend becoming more prominent and widened out, and eventually dividing into two well-marked ridges, which constitute the upper boundaries of the popliteal space, and are formed by the tendons of the inner and outer hamstring muscles respectively. In the upper part of the thigh these muscles are not to be individually distinguished from each other, but lower down the separation between the Semitendinosus and Semimembranosus is denoted by a slight intermuscular marking. The external hamstring tendon formed by the **Biceps** is seen as a thick cord running down to the head of the fibula. The inner hamstring tendons comprise the Semitendinosus, the Semimembranosus, and the Gracilis. The **Semitendinosus** is the most internal of these, and can be felt, in certain positions of the limb, as a sharp cord; the **Semitendinosus** is thick, and the Gracilis is situated a little farther forward than the other two. All the muscles on the front of the leg appear to a certain extent somewhere on the surface, but the form of this region is mainly dependent upon the Tibialis anticus and the Extensor longus digitorum. The **Tibialis anticus** is well marked, and presents a fusiform enlargement at the outer side of the tibia, and projects beyond the crest of the shinbone. From the muscular mass its tendons may be traced downward, standing out boldly, when the muscle is in action, on the front of the tibia and ankle-joint, and coursing down to its insertion along the inner border of the foot. A well-marked groove separates this muscle externally from the **Extensor longus digitorum**, which fills up the rest of the space between the upper part of the shaft of the tibia and fibula. It does not present so bold an outline as the Tibialis anticus, and its tendon below, diverging from the tendon of the Tibialis anticus, forms with the latter a sort of plane, in which may be seen the tendon of the Extensor proprius hallucis. A groove on the outer side of the extensor longus digitorum, seen most plainly when the muscle is in action, separates the tendon from a slight eminence corresponding to the **Peroneus tertius**. The fleshy fibres of the **Peroneus longus** are strongly marked at the upper part of the outer
side of the leg, especially when the muscle is in action. It forms a bold swelling, separated by furrows from the Extensor longus digitorum in front and the Soleus behind. Below, the fleshy fibres terminate abruptly in a tendon which overlaps the more flattened form of the Peroneus brevis. At the external malleolus the tendon of the Peroneus brevis is more marked than that of the Peroneus longus. On the dorsum of the foot the tendons of the Extensor muscles, emerging from beneath the anterior annular ligament, spread out and can be distinguished in the following order: The most internal and largest is the Tibialis anticus, then the Extensor proprius hallucis; next comes the Extensor longus digitorum, dividing into four tendons to the four outer toes; and lastly, most externally, is the Peroneus tertius. The flattened form of the dorsum of the foot is relieved by the rounded outline of the fleshy belly of the Extensor brevis digitorum, which forms a soft fulness on the outer side of the tarsus in front of the external malleolus, and by the Dorsal interosseus, which bulge between the metatarsal bones. At the back of the knee is the popliteal space, bounded above by the tendons of the hamstring muscle; below, by the two heads of the Gastrocnemius. Below this space is the prominent fleshy mass of the calf of the leg, produced by the Gastrocnemius and Soleus. When these muscles are in action, as in standing on tiptoe, the borders of the Gastrocnemius are well defined, presenting two curved lines, which converge to the tendon of insertion. Of these borders, the inner is more prominent than the outer. The fleshy mass of the calf terminates somewhat abruptly below in the tendon Achilles, which stands out prominently on the lower part of the back of the leg. It presents a somewhat tapering form in the upper three-fourths of its extent, but widens out slightly below. When the muscles of the calf are in action, the lateral portions of the Soleus may be seen, forming curved eminences, of which the outer is the longer, on either side of the Gastrocnemius. Behind the inner border of the lower part of the shaft of the tibia a well-marked ridge, produced by the tendon of the Tibialis posticus, is visible when this muscle is in a state of contraction. On the sole of the foot the superficial layer of muscles influences surface form; the Abductor minimi digitii most markedly. This muscle forms a narrow rounded elevation along the outer border of the foot, while the Abductor hallucis does the same, though to a less extent, on the inner side. The Flexor brevis digitorum, bound down by the plantar fascia, is not very apparent; it produces a flattened form, covered by the thickened skin of the sole, which is here thrown into numerous wrinkles.

**SURGICAL ANATOMY OF THE LOWER EXTREMITY.**

The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fractures are selected for illustration and description.

---

**In fracture of the neck of the femur internal to the capsular ligament** (Fig. 359) the characteristic marks are slight shortening of the limb and eversion of the foot, neither of which symp-
THE MUSCLES AND FASCIAE

toms occurs, however, in some cases until some time after the injury. The eversion is caused by the weight of the limb rotating it outward. The shortening is produced by the action of the Glutei, and by the Rectus femoris in front and the Biceps, Semitendinosus, and Semimembranosus behind. The treatment is extension by means of adhesive plaster and weights and counter-extension by raising the foot of the bed, eversion being corrected by sand-bags. In some cases Thomas's splint is used.

In fracture of the femur just below the trochanters (Fig. 360) the upper fragment, the portion chiefly displaced, is tilted forward almost at right angles with the pelvis by the combined action of the Psoas and Iliacus, and, at the same time, everted and drawn outward by the External rotator and Glutei muscles, causing a marked prominence at the upper and outer side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, in consequence of the lower fragment being drawn upward by the rectus in front, and the Biceps, Semimembranosus, and Semitendinosus behind, and is at the same time everted. This fracture may be reduced by direct relaxation of all the opposing muscles, to effect which the limb should be put up in such a manner that the thigh is flexed on the pelvis and the leg on the thigh, the extremity being placed upon a double inclined plane and extension being made in the axis of the partly flexed thigh by means of adhesive plaster and weights. In some cases it is necessary to incise and wire the fragments together.

Oblique fracture of the femur immediately above the condyles (Fig. 361) is a formidable injury, and attended with considerable displacement. On examination of the limb the lower fragment may be felt deep in the popliteal space, being drawn backward by the Gastrocnemius and Plantaris muscles, and upward by the Hamstring and Rectus muscles. The pointed end of the upper fragment is drawn inward by the Pectineus and Adductor muscles, and tilted forward by the Psoas and Iliacus, piercing the Rectus muscle and occasionally the integument. Relaxation of these muscles and direct approximation of the broken fragments are effected by placing the limb on a double inclined plane. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed from the Rectus muscle being held down by the fractured end of the bone, and from the patella, when elevated, being drawn upward against the projecting fragment.

In fracture of the patella (Fig. 362) the fragments are separated by the effusion which takes place into the joint, and by the action of the Quadriceps extensor; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone. Some cases may be treated by a posterior straight splint, the fragments being pulled together by strips of adhesive plaster. In many cases it is advisable to incise, remove intervening pieces of fibrous tissue and wire the fragments together.
The tibia is fractured most commonly by indirect force at the junction of the middle third with the lower third of the shaft. Compound fractures are more common in the leg than in any other region of the body because the tibia is such a superficial bone and is so much exposed to injury. Most fractures from indirect force are oblique.

In oblique fracture of the shaft of the tibia (Fig. 363), if the fracture has taken place obliquely from above, downward and forward, the fragments ride over one another, the lower fragments being drawn backward and upward by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forward immediately beneath the integument, often protruding through it and rendering the fracture a compound one. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forward, riding upon the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is often necessary, however, in a compound fracture, to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

Fracture of the fibula with dislocation of the foot outward (Fig. 364), commonly known as Pott's fracture, is one of the most frequent injuries of the ankle-joint. The fibula is fractured about three inches above the ankle; in addition to this the internal malleolus is broken off, or the deltoid ligament torn through, and the end of the tibia displaced from the corresponding surface of the astragalus. The foot is markedly everted, and the sharp edge of the upper end of the fractured malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury can generally be reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counter-extension at the knee.
THE BLOOD-VASCULAR SYSTEM.

ANGIOLOGY is the branch of anatomy which treats of the blood-vessels. The blood-vascular system comprises the heart and blood-vessels with their contained fluid, the blood.

The Heart is the central organ of the entire system, and is a hollow muscle; by its contraction the blood is pumped to all parts of the body through a complicated series of tubes, termed arteries. The arteries undergo almost infinite ramification in their course throughout the body, and end in very minute vessels, called arterioles, which in their turn open into a close-meshed network of microscopic vessels, termed capillaries. After the blood has passed through the capillaries it enters into minute vessels called venules and from them it is collected into a series of larger vessels, called veins, by which it is returned to the heart. The passage of the blood through the heart and blood-vessels constitutes what is termed the circulation of the blood, of which the following is an outline.

The human heart is divided by a septum into two halves, right and left, each half being further constricted into two cavities, the upper of the two being termed the auricle and the lower the ventricle. The heart therefore consists of four chambers or cavities, two forming the right half, the right auricle and right ventricle; and two the left half, the left auricle and left ventricle. The right half of the heart contains venous or impure blood; the left, arterial or pure blood. From the cavity of the left ventricle the pure blood is carried into a large artery, the aorta, through the numerous branches of which it is distributed to all parts of the body, with the exception of the lungs. In its passage through the capillaries of the body the blood gives up to the tissues the materials necessary for their growth and nourishment, and at the same time receives from the tissues the waste products resulting from their metabolism, and in doing so becomes changed from arterial or pure blood into venous or impure blood, which is collected by the veins and through them returned to the right auricle of the heart. From this cavity the impure blood passes into the right ventricle, from which it is conveyed through the pulmonary arteries to the lungs. In the capillaries of the lungs it again becomes arterialized, and is then carried to the left auricle by the pulmonary veins. From this cavity it passes into that of the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or systemic circulation, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or pulmonary circulation.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is collected into a large vein, termed the portal vein, by which it is carried to the liver. In the liver this vein divides, after the manner of an artery, and ultimately ends in capillary vessels, from which the rootlets of a series of veins, called the hepatic veins, arise; these carry the blood into the inferior vena cava, which conveys it to the right auricle.
From this it will be seen that the blood contained in the portal vein passes through two sets of capillary vessels: (1) those in the spleen, pancreas, stomach, etc., and (2) those in the liver.

Speaking generally, the arteries may be said to contain pure, and the veins impure, blood. This is true of the systemic, but not of the pulmonary, vessels, since it has been seen that the impure blood is conveyed from the heart to the lungs by the pulmonary arteries, and the pure blood returned from the lungs to the heart by the pulmonary veins. Arteries, therefore, must be defined as vessels which convey blood from the heart, and veins as vessels which return blood to the heart.

The heart and lungs are contained within the cavity of the thorax, the walls of which afford them protection (Fig. 306). The heart lies between the two lungs, and is there enclosed within a sero-membranous bag, the pericardium, while each lung is invested by a serous membrane, the pleura. The skeleton of the thorax was described on page 155.

The Cavity of the Thorax (cavum thoracis).—The capacity of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity extends above the first rib into the neck. The size of the cavity of the thorax is constantly varying during life, with the movements of the ribs and diaphragm, and with the degree of distention of the abdominal viscera. From the collapsed state of the lungs, as seen when the thorax is opened, in the dead body, it would appear as if the viscera only partly filled the cavity of the thorax, but during life there is no vacant space, that which is seen after death being filled up during life by the expanded lungs.

The Upper Opening of the Thorax (apertura thoracis superior).—The parts which pass through the upper opening of the thorax are, from before backward in or near the middle line, the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the trachea, oesophagus, thoracic duct, the inferior thyroid veins, and the Longus colli muscle of each side; at the sides, the innominate artery, the left common carotid, and left subclavian arteries, the internal mammary and superior intercostal arteries, the right and left innominate veins, the pulmonary, cardiac, phrenic, and sympathetic nerves, the anterior branch of the first dorsal nerve, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the margin of the first rib.

The Lower Opening of the Thorax (apertura thoracis inferior) is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The
Diaphragm (see page 427) closes in the opening, forming the floor of the thorax. The floor is flatter at the centre than at the sides, and is higher on the right side than on the left, corresponding in the dead body to the upper border of the fifth costal cartilage on the former, and to the corresponding part of the sixth costal cartilage on the latter. From the highest point on each side the floor slopes suddenly downward to the attachment of the Diaphragm to the ribs; this is more marked behind than in front, so that only a narrow space is left between it and the wall of the thorax.

THE PERICARDIUM.

The pericardium (Figs. 367, 368, 369, 370, 371, and 372) is a conical seromembranous sac, placed in the middle mediastinum. In this sac the heart and the commencement of the great vessels are contained. It is placed behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleurae.

Its apex is directed upward, and surrounds the great vessels about two inches above their origin from the base of the heart. Its base is attached to the central tendon and to the left part of the adjoining muscular structure of the Diaphragm. In front it is separated from the sternum by the remains of the thymus gland.

Fig. 366.—Front view of the thorax. The ribs and sternum are represented in relation to the lungs, heart, and other internal organs. 1. Pulmonary orifice. 2. Aortic orifice. 3. Left auriculo-ventricular orifice. 4. Right auriculo-ventricular orifice.
above and a little loose areolar tissue below, and is covered by the margins of the lungs, especially the left. Behind, it rests upon the bronchi, the oesophagus, and the descending aorta. Laterally, it is covered by the pleurae, and is in relation to the inner surface of the lungs; the phrenic nerve with its accompanying vessels descends between the pericardium and pleura on either side (Fig. 371).

**Structure of the Pericardium.**—The pericardium is a fibro-serous membrane, and consists, therefore, of two layers, an external fibrous and an internal serous.

The **Fibrous Layer** is a strong, dense, connective-tissue membrane. Above, it surrounds the great vessels arising from the base of the heart, on which it is continued in the form of tubular prolongations which are gradually lost upon their external coat, the strongest being that which encloses the aorta. The pericardium may be traced over these vessels, to become continuous with the deep layer of the cervical fascia. The prolongations to the cervical fascia constitute the **vertebro-pericardial ligaments** (Fig. 370). In front the pericardium is connected to the posterior surface of the sternum by two fibrous bands, the **superior** and **inferior sterno-pericardiac ligaments** or **ligaments of Luschka** (*ligamenta sternopericardicae*) (Fig. 370). The superior sterno-pericardial ligament, called also the **sternocosto-**
pericardial ligament (Fig. 370), passes to the manubrium. The inferior sterno-pericardial ligament, called also the xipho-pericardial ligament (Fig. 370), passes to the ensiform cartilage. On each side of the ascending aorta the pericardium sends upward a diverticulum: the one on the left side, somewhat conical in shape, passes upward and outward, between the arch of the aorta and the pulmonary artery, as far as the ductus arteriosus, where it terminates in a cecal extremity, which is attached by loose connective tissue to the obliterated duct (Fig. 367). The one on the right side passes upward and to the right, between the ascending aorta and

vena cava superior, and also terminates in a cecal extremity. Below, the fibrous layer is attached to the central tendon of the Diaphragm, and on the left side to its muscular fibres. The pericardium is fixed to the Diaphragm by the anterior phreno-pericardial ligament and by the lateral phreno-pericardial ligaments (Fig. 370).

The vessels receiving fibrous prolongations from this membrane are the aorta the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. The inferior vena cava enters the pericardium through the central tendon of the Diaphragm, and consequently it receives no covering from the fibrous layer (Fig. 371).
The Serous Pericardium invests the heart, and is then reflected on the inner surface of the fibrous pericardium. It consists, therefore, of a visceral layer (epicardium) and a parietal layer. The former invests the surface of the heart, and the commencement of the great vessels, to the extent of an inch and a half from their origin; from these it is reflected upon the inner surface of the fibrous layer. The serous membrane encloses the aorta and pulmonary artery in a single tube, so that a passage, termed the great transverse sinus of the pericardium (sinus transversus pericardii), exists between these vessels in front and the auricle behind. This sinus is closed above and below but often to the right and left. The membrane only partially covers the superior vena cava and the four pulmonary veins, and scarcely covers the inferior cava, as this vessel enters the heart almost directly after it has passed through the Diaphragm. A deep blind recess formed by the serous pericardium is found behind the heart when that organ is raised up. This recess runs backward between the left auricle and the posterior portion of the fibrous pericardium, and forms a diverticulum between the heart and the oesophagus. This recess is called the oblique sinus. It passes upward between the inferior vena cava and the lower left pulmonary vein and terminates between the right and left pulmonary veins. The inner surface of the pericardium is covered with endothelium, which rests upon a mixture of fibrous and elastic tissue, which is smooth and glistening, and secretes a serous fluid (liquor
THE PERICARDIUM

561

pericardii), which serves to facilitate the movements of the heart. In the serous layer of the pericardium are many blood-vessels, lymph vessels, and nerves.

Arteries of the Pericardium.—These are derived from the internal mammary and its musculo-phrenic branch, and from the descending thoracic aorta.

Nerves of the Pericardium.—These are branches from the vagus, the phrenic, and the sympathetic.

The Vestigial Fold of the Pericardium.—Between the left pulmonary artery and subjacent pulmonary vein and behind the left extremity of the transverse sinus is a triangular fold of the serous pericardium; it is known as the vestigial fold of Marshall (ligamentum v. cavae sinistri). It is formed by the duplicature of the serous layer over the remnant of the lower part of the left superior vena cava

(v. cava sinistra) or the duct of Cuvier, which, after birth, becomes obliterated, and remains as a fibrous band stretching from the left superior intercostal vein to the left auricle, where it is continuous with a small vein, the oblique vein of Marshall (v. obliqua atrii sinistri [Marshallii]), which opens into the coronary sinus and is a remnant of the foetal left superior vena cava.

Surgical Anatomy.—Aspiration of the pericardium (paracentesis of the pericardium) is occasionally though seldom performed. It is only to be thought of when pericardial effusion endangers life. The operation is very dangerous, because the effusion lifts the heart and pushes it forward.

36
and the needle is apt to wound the heart or even enter one of the cavities. There is also danger of wounding the internal mammary artery. The operation is never to be thought of in purulent pericarditis. The safest way to aspirate is to introduce the needle in the fifth interspace two inches to the left of the sternum and push it straight backward.

A better operation, even in a case of serous effusion, and one invariably selected in purulent pericarditis, is incision (pericardotomy). A portion of the cartilage of the fifth rib of the left side is excised. The pericardium is exposed and is punctured, to learn the nature of the contained fluid, and is then incised. By this method the surgeon avoids opening the pleural cavity, and can obtain free drainage if pus is found.

Porter maintains that by "reason of the uncertain and varying relations of the pleura, and also of the anterior position of the heart, whenever the pericardial sac is distended with fluid, aspiration of the pericardium is a much more dangerous procedure than open incision when done by skilled hands."

![Diagram of the heart and pericardium](image_url)

**Fig. 371.—Posterior wall of the pericardium, after the removal of the heart, showing the relation of the serous pericardium to the great vessels.** (From a formalin preparation by Prof. Birmingham.) (Cunningham.)

**THE HEART (COR).**

The heart is a hollow muscular organ of a conical form, placed between the lungs, and enclosed in the cavity of the pericardium.

**Position (Fig. 372).—**The heart is placed obliquely in the chest: the broad attached end, or base (basis cordis), is directed upward, backward, and to the right, and corresponds with the dorsal vertebrae, from the fifth to the eighth inclusive; the apex (apex cordis) is directed downward, forward, and to the left, and corresponds to the space between the cartilages of the fifth and sixth ribs, three-quarters of an
inch to the inner side, and an inch and a half below the left nipple, or about three and a half inches from the middle line of the sternum. The heart is placed behind the sternum, and projects farther into the left than into the right half of the cavity of the chest, extending from the median line about three inches in the former direction, and only one and a half in the latter; about one-third of the heart lies to the right and two-thirds to the left of the mesial plane. The antero-superior surface (facies sternocostalis) is round and convex, directed upward and forward, is formed chiefly by the right auricle and ventricle, together with a small part of the left ventricle. It lies behind the middle portion of the sternum and the costal cartilages of the third, fourth, fifth, and sixth ribs on both sides. On account of

Fig. 372.—Position of the heart. The pericardium laid open. Adult male. (Poirier and Charpy.)

the heart’s inclination to the left side, only a small part of it lies behind the cartilages of the right ribs. Lying in front of the heart, between it and the anterior chest-wall, is the thin anterior margin of the lungs, covered by the pleura. On the left side, however, owing to the notch in the anterior margin of the left lung (incisura cardiaca), there is a portion of the pericardium lying in contact with the Triangularis sterni muscle. This area is called the area of greatest or of absolute cardiac dulness or the area of superficial cardiac dulness. The postero-inferior surface of the heart (facies diaphragmatica), which looks downward rather
than backward, is flattened and rests upon the Diaphragm, and is formed chiefly by the left ventricle. The right or lower border is long, thin, and sharp; the left or upper border short, but thick and round.

**Size and Weight.**—The heart, in the adult, measures five inches in length, three inches and a half in breadth in the broadest part, and two inches and a half in thickness. The prevalent weight, in the male, varies from ten to twelve ounces; in the female, from eight to ten: its proportions to the body being as 1 to 169 in males; 1 to 149 in females. The heart continues increasing in weight, and also in length, breadth, and thickness, up to an advanced period of life: this increase is more marked in men than in women.

**Capacity of the Cavities of the Heart.**—This matter is in dispute. Professor Cunningham believes that during life the capacity of the ventricles is nearly identical, each holding about four ounces of blood. Each auricle holds a little less than four ounces. Stewart maintains that at each heart beat each ventricle throws out only eighty-seven grams of blood. Morrant Baker says that, “taking the mean of various estimates, it may be inferred that each ventricle is able to contain four to six ounces of blood.”

**Fat upon the Heart.**—Normally there is a certain amount of fat upon the surface of the heart. This begins to appear in the early weeks of life and increases in amount as age advances. It is found upon the surface of the muscles and along the course of the vessels. Poirier is of the opinion that the cardiac fat on the anterior surface of the heart is arranged in three movable

---

1 Kirke's Physiology, 10th ed., p. 156.
pads, which act as valves and fill vacant spaces about the heart created during the cardiac contractions.¹

**Component Parts.**—The heart is subdivided by a muscular septum into two lateral halves, which are named respectively the **right** or pulmonary heart and the **left** or systemic heart; and a transverse constriction subdivides each half of the organ into two cavities, the upper cavity on each side being called the **auricle**, the lower the **ventricle**. The course of the blood through the heart cavities and blood-vessels has already been described (page 555).

The division of the heart into four cavities is indicated by grooves upon its surface. The groove separating the auricles from the ventricles is called the **auriculo-ventricular groove** (sulcus coronarius). It is deficient, in front, where it is crossed by the root of the pulmonary artery. It contains the trunks of the nutrient vessels of the heart. The auricular portion occupies the base of the heart, and is subdivided into two cavities by a median septum. The two ventricles are also separated into a right and left by two furrows, the **interventricular grooves** (sulci longitudinalis), which are situated one on the anterior (sulcus longitudinalis anterior), the other on the posterior (sulcus longitudinalis posterior) surface; these extend from the base of the ventricular portion to near the apex of the organ; the former being situated nearer to the left border of the heart, and the latter to the right. It follows, therefore, that the right ventricle forms the greater portion of the anterior surface of the heart, and the left ventricle more of its posterior surface. The internal surface of the heart is lined with endocardium.

The **auricular portion** occupies the base of the heart and is subdivided into two cavities or **auricles** (atria) by a septum. As before stated, this portion of the heart corresponds to the middle segment of the dorsal spine. Its form is quadrilateral in shape, and has two processes extending upward from its two upper angles, called the **auricular appendices** (appendices auriculares), between which are found the aorta and the pulmonary artery. The greater part of the base of the heart is formed by the left auricle. Its boundaries are, above, the pulmonary artery; below, the coronary sinus; on the left it is bounded by the left superior and inferior pulmonary veins, while on the right side it is limited by the **sulcus terminalis**. The latter corresponds to a ridge in the interior of the auricle, called the **crista terminalis**. Running vertically on this surface, just to the left of the openings of the two vena cavae, is the **interauricular furrow**, which exactly indicates the proportion of the base of the heart formed by each auricle.

Each of the cavities should now be separately examined.

The **Right Auricle**² (atrium dexterum) is a little larger than the left, its walls somewhat thinner, measuring about one line. It consists of two parts: a principal cavity, the **sinus venosus**, situated posteriorly, and an anterior, smaller portion, the **appendix auriculae**. The right auricle is separated from the left auricle by the **interauricular septum** (septum atriorum). Part of this septum is muscular; part is composed of connective tissue.

The **sinus venosus** (sinus venaarum) is the large quadrangular cavity, placed between the two vena cavae; its walls are extremely thin; it is connected below with the right ventricle, and internally with the left auricle, being free in the rest of its extent. It is derived from a portion of the **sinus reuniens** of the fetal heart.

The **right auricular appendix** (auricula dextra), so-called from its fancied resemblance to a dog's ear, is a small conical muscular pouch, the margins of which present a dentated edge. It projects from the sinus forward and to the left side, overlapping the root of the aorta.

¹ L'appareil sero-graisseux. La Presse Médicale, December 7, 1904.
² In the new nomenclature the auricle is called the atrium, and auricular appendix is called the auricle.
To examine the interior of the right auricle, an incision should be made along its right border, from the entrance of the superior vena cava to that of the inferior. A second cut is to be made from the centre of this first incision to the tip of the auricular appendix, and the flaps raised.

The internal surface of the right auricle is smooth, except in the appendix and adjacent part of the anterior wall of the sinus venosus, where the muscular wall is thrown into parallel ridges resembling the teeth of a comb and hence named the \textit{musculi pectinati}. These end behind on a vertical smooth ridge, the \textit{crista terminalis} of His, the position of which is indicated on the surface of the distended auricle by a furrow, the \textit{sulcus terminalis} of His. The sulcus terminalis passes from in front of the superior vena cava to the left of the inferior vena cava. It represents the line of fusion of the sinus venosus of the embryo with the primitive auricle proper.

The right auricle presents the following parts for examination:

\begin{align*}
\text{Openings} & \quad \text{Superior cava.} \\
& \quad \text{Inferior cava.} \\
& \quad \text{Coronary sinus.} \\
& \quad \text{Foramini Thebesii.} \\
& \quad \text{Auriculo-ventricular.} \\
\text{Valves} & \quad \text{Eustachian.} \\
& \quad \text{Coronary.} \\
& \quad \text{Fossa ovalis.} \\
& \quad \text{Annulus ovalis.} \\
& \quad \text{Tuberculum Loweri.} \\
& \quad \text{Musculi pectinati.}
\end{align*}

The \textit{superior vena cava} returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downward and forward. The superior vena cava does not possess valves.

The \textit{inferior vena cava}, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the auricle near the
septum, the direction of its orifice being upward and inward. The direction of a current of blood through the superior vena cava would consequently be toward the auriculo-ventricular orifice, whilst the direction of the blood through the inferior vena cava would be toward the auricular septum. This is the normal direction of the two currents in foetal life. The inferior vena cava does not possess valves until its termination at the right auricle.

The **coronary sinus** (sinus coronarius) opens into the auricle, between the inferior vena cava and the auriculo-ventricular opening. It returns the blood from the substance of the heart, and is protected by a semicircular fold of the lining membrane of the auricle, the **coronary valve** or **valve of Thebesius**. The sinus, before entering the auricle, is considerably dilated—nearly to the size of the end of the little finger. Its wall is partly muscular, and at its junction with the great coronary vein it is somewhat constricted and is furnished with a valve consisting of two unequal segments.

The **foramini Thebesii** (foramina venarum minimarum) are numerous minute fossae or apertures on various parts of the inner surface of the auricle. Many of these foramini have at their points the minute openings of small veins (venae minimae cordis). They return the blood directly from the muscular substance of the heart. Some of these foramini are minute depressions in the walls of the heart, presenting a closed extremity.

The **right auriculo-ventricular opening** or the **tricuspid orifice** (ostium venosum dextrum) is the large oval aperture of communication between the right auricle and the ventricle, to be presently described.

The **Eustachian valve** (valvula vena cava inferioris [Eustachii]) is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. It is semilunar in form, its convex margin being attached to the wall of the vein; its concave margin, which is free, terminating in two cornua, of which the left is attached to the anterior edge of the annulus ovalis, the right being lost on the wall of the auricle. The valve is formed by a duplication of the lining membrane of the auricle and contains a few muscular fibres.

**In the fetus** this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle.

**In the adult** it is occasionally large, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and its free margin presents a cribriform or filamentous appearance; occasionally it is altogether wanting.

The **coronary valve** or **valve of Thebesius** (valvula sinus coronarii [Thebesii]) is a semicircular fold of the lining membrane of the auricle, protecting the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve is occasionally double.

The **fossa ovalis** is an oval depression corresponding to the situation of the **foramen ovale** in the foetus. It is situated at the lower part of the septum atrium, above and to the left of the orifice of the inferior vena cava. In foetal life an opening, the **foramen ovale**, exists at this point between the two auricles; almost immediately after birth the valve-like edge is pressed down by the increased pressure in the left auricle and by the tenth day it passes to the annulus and closes the opening.

The **annulus ovalis** (limbus fossae ovalis [Vieussenii]) is a prominent oval margin which surrounds anteriorly and superiorly the fossa ovalis. It is most distinct above and at the sides; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa ovalis, which leads upward beneath the annulus into the left auricle, and is the remains of the aperture between the two auricles in the foetus.
The tubercle of Lower (tuberculum intervenosum [Loweri]) is a small projection on the interauricular septum between the fossa ovalis and the opening of the superior vena cava. It is most distinct in the hearts of quadrupeds; in man it is scarcely visible. It was supposed by Lower to direct the blood from the superior cava toward the auriculo-ventricular opening.

The Left Auricle (atrium sinistrum) is rather smaller than the right; its walls are thicker, measuring about one line and a half; and it consists, like the right, of two parts, a principal cavity, or sinus, and an appendix auriculae.

The sinus is cuboidal in form, and concealed in front by the pulmonary artery and aorta; internally, it is separated from the right auricle by the septum auricularum (septum atriorum); behind, it receives on each side two pulmonary veins, being free in the rest of its extent.

The left auricular appendix (auricula sinistra) is somewhat constricted at its junction with the auricle; it is longer, narrower, and more curved than that of the right side, and its margins are more deeply indented, presenting a kind of foliated appearance. Its direction is forward and toward the right side, overlapping the root of the pulmonary artery.

Within the auricle the following parts present themselves for examination:

The openings of the four pulmonary veins.
Auriculo-ventricular opening.
Musculi pectinati.
Foramina Thebesii.

The pulmonary veins, four in number, open, two into the right and two into the left side of the auricle. The two left veins frequently terminate by a common opening. They are not provided with valves.

The auriculo-ventricular opening or mitral orifice (ostium venosum ventriculi sinistri) is the large oval aperture of communication between the left auricle and the left ventricle. It is rather smaller than the corresponding opening on the opposite side (see note, page 569).

The musculi pectinati are fewer in number and smaller than on the right side; they are confined to the inner surface of the auricular appendix.

On the inner surface of the septum atriorum may be seen a lunated impression bounded below by a crescentic ridge the concavity of which is turned upward. The depression is just above the fossa ovalis in the right auricle. The inner surface of the auricle shows foramina Thebesii and venæ minimæ cordis.

To examine the interior of the left ventricle, make an incision a little to the left of the anterior interventricular groove from the base to the apex of the heart, and carry it up from thence, a little to the left of the posterior interventricular groove, nearly as far as the auriculo-ventricular groove.

The ventricular portion of the heart is conical in shape with its base extending backward and upward and fitting against the atrii of the auricles. Its apex constitutes the apex of the heart (apex cordis) and extends to the fifth intercostal space three and a quarter inches to the left of the middle line. The ventricles are thick and muscular and have an antero-superior surface (facies sternalis) and a postero-inferior surface (facies diaphragmatica) and two borders, a right and a left border. The antero-superior surface is composed mainly of the right ventricle; coursing on this surface, nearer the left border than the right from the auriculo-ventricular groove to the apex, is the anterior interventricular groove (suleus longitudinalis anterior). The inferior surface rests on the diaphragm and is chiefly made by the left ventricle; it is also traversed by a groove called the inferior or posterior interventricular groove (suleus longitudinalis posterior). The two grooves meet in a groove (incisura apicis cordis) at the right side of the
apex of the heart. Of the two borders of the ventricular portion the right is sharp and thin (margo acutus) and is a continuation of the sulcus terminalis of the base of the heart. It extends from right to left. The left border is thick and rounded (margo obtusus). The base of the ventricles is perforated by four large openings, namely, the aorta, the pulmonary artery, the right and left auriculo-ventricular openings.

The Right Ventricle (ventriculus dexter) is triangular in form, and extends from the right auricle to near the apex of the heart. Its antero-superior surface is rounded and convex, and forms the larger part of the front of the heart. Its inferior surface is flattened, rests upon the Diaphragm, and forms only a small part of the back of the heart. Its posterior wall is formed by the partition between the two ventricles, the interventricular septum (septum ventriculorum), so that a transverse section of the cavity presents a semilunar outline. The surface of the septum is convex and bulges into the cavity of the right ventricle. The upper and inner angle of the ventricle is prolonged into a conical pouch, the infundibulum (conus arteriosus), from which the pulmonary artery arises. The balance of the ventricle, the body, is the portion into which the auriculo-ventricular orifice opens. The conus arteriosus is marked off from the body of the ventricle by a muscular projection (crista supraventricularis). The walls of the right ventricle are thinner than those of the left, the proportion between them being as 1 to 3. The wall is thickest at the base, and gradually becomes thinner toward the apex.

To examine the interior of the right ventricle, its anterior wall should be turned downward and to the right in the form of a triangular flap. This is accomplished by making two incisions: (1) from the pulmonary artery to the apex of the ventricle parallel to, but a little to the right of, the anterior interventricular furrow; (2) another, starting from the upper extremity of the first and carried outward parallel to, but a little below, the auriculo-ventricular furrow, care being taken not to injure the auriculo-ventricular valve.

The following parts present themselves for examination:

\[\text{Openings} \begin{cases} \text{Auriculo-ventricular.} \\ \text{Opening of the pulmonary artery.} \end{cases} \]

\[\text{Valves} \begin{cases} \text{Tricuspid.} \\ \text{Semilunar.} \end{cases} \]

And a muscular and tendinous apparatus connected with the tricuspid valve:

\[\text{Columnae carneae.} \quad \text{Chordee tendineae.} \]

The right auriculo-ventricular opening or the tricuspid orifice (ostium venosum ventriculi dextri) is the large oval aperture of communication between the auricle and ventricle. It is situated at the base of the ventricle, near the right border of the heart. It is about an inch and a half in diameter,\(^1\) oval from side to side, surrounded by a fibrous ring and covered by the lining membrane of the heart; it is considerably larger than the corresponding aperture on the left side, being sufficient to admit the ends of four fingers. It is guarded by the tricuspid valve.

The opening of the pulmonary artery (ostium arteriosum) is circular in form, and is situated at the summit of the conus arteriosus, close to the septum ventriculorum. It is placed above and on the left side of the auriculo-ventricular

\(^1\) In the Pathological Transactions, vol. vi, p. 110, Dr. Peacock has given some careful researches upon the weight and dimensions of the heart in health and disease. He states, as a result of his investigations, that in the healthy adult heart the right auriculo-ventricular aperture has a mean circumference of 64.4 lines, or \(4^{29/36}\) inches; the left auriculo-ventricular aperture a mean circumference of 44.3 lines, or \(3^{29/36}\) inches; the pulmonary orifice of 40 lines, or \(3^{29/36}\) inches; and the aortic orifice of 35.5 lines, or \(3^{29/36}\) inches; but the dimensions of the orifices varied greatly in different cases, the right auriculo-ventricular aperture having a range of from 40 to 50 lines, and the others in the same proportion.—Ed. of 15th English edition.
opening, upon the anterior aspect of the heart. Its orifice is guarded by the pulmonary semilunar valves.

The tricuspid valve (valvula tricuspidalis) consists of three segments or cusps (cuspides) of a triangular or trapezoidal shape, each formed by a duplication of the lining membrane of the heart, strengthened by a layer of fibrous tissue, which contains, according to Kürschner and Senac, muscular fibres. These segments are connected by their bases to the oval fibrous ring surrounding the auriculo-ventricular orifice (annulus fibrosus dexter), and by their sides with one another, so as to form a continuous annular membrane, which is attached round the margin of the auriculo-ventricular opening, their free margins and ventricular surfaces affording attachment to a number of delicate tendinous cords, the chordae tendineae. The largest and most movable segment is placed toward the left side of the auriculo-ventricular opening, and is interposed between that opening and the infundibulum; hence it is called the left or infundibular cusp (cuspis medialis). Another segment corresponds to the right part of the front of the ventricle, the right or marginal cusp (cuspis anterior), and a third to its posterior wall, the posterior or septal cusp (cuspis posterior). The central part of each segment is thick and strong: the lateral margins are thin and translucent. The chordae tendineae are connected with the adjacent margins of the principal segments of the valve, and are further attached to each segment in the following manner: 1. Three or four reach the attached margin of each segment, where they are continuous with the auriculo-ventricular tendinous ring. 2. Others, four to six in number, are attached to the central thickened part of each segment. 3. The most numerous and finest are connected with the marginal portion of each segment.

The columnae carneae (trabeculae carneae) are the rounded muscular columns which project from nearly the whole of the inner surface of the ventricle, excepting near the opening of the pulmonary artery, where the wall is smooth. They may be classified, according to their mode of connection with the ventricle, into three sets. The first set merely forms prominent ridges on the inner surface of the ventricle, being attached by their entire length on one side, as well as by their extremities. The second set are attached by their two extremities, but are free in the rest of their extent; while the third set (musculi papillares) are attached by one extremity to the wall of the heart, the opposite extremity giving attachment to the chordae tendineae. There are two papillary muscles, the anterior and the posterior: of these, the anterior is the larger; its chordae tendineae are connected with the right and left segments of the tricuspid valve. The posterior is not always single, but sometimes consists of two or three muscular columns; its chordae tendineae are connected with the posterior and the right segments of the tricuspid valve. In addition to these, some few chordae may be seen springing directly from the ventricular septum, or from small eminences on it, and passing to the left and posterior segments. A fleshy band, well marked in the ox and some other animals, is frequently seen passing from the base of the anterior papillary muscle to the interventricular septum. From its attachments it may assist in preventing overdistention of the auricle, and so has been named the moderator band.

The right auriculo-ventricular orifice allows the blood to pass freely from the right auricle into the right ventricle, and it will be noted that the surface of the tricuspid valve next the blood-current is quite smooth. When the right ventricle contracts to force the blood into the pulmonary artery, the segments of the tricuspid valve come together and close the auriculo-ventricular opening, and so prevent the blood from passing back into the auricle. The papillary muscles and chordae tendineae moor the segments of the valve and prevent their being forced through into the auricle by the weight of blood behind them.
The *semilunar valves* (valvulae semilunares a. pulmonalis), three in number, guard the orifice of the pulmonary artery. They consist of three semicircular folds: two of which are *anterior* and one of which is *posterior*. They are formed by duplicatures of the lining membrane of the ventricle, strengthened by fibrous tissue. They are attached, by their convex margins, to the wall of the artery, at its junction with the ventricle, the straight border being free, and directed upward in the lumen of the vessel. The free margin of each is somewhat thicker than the rest of the valve, is strengthened by a bundle of tendinous fibres, and presents, at its middle, a small projecting thickened nodule, consisting of bundles of interlacing connective-tissue fibres with branched connective-tissue cells and some few elastic fibres. Such a nodule is called the *corpus Arantii* or *body of Arangi* (nodulus valvulae semilunaris [Arantii]). From this nodule tendinous fibres radiate through the valve to its attached margin, and these fibres form a constituent part of its substance throughout its whole extent, excepting two narrow lunated portions, the *lunula* (lunulae valvularum semilunariae), placed one on each side of the nodule immediately adjoining the free margin; here the valve is thin, and formed merely by the lining membrane. During the passage of the blood along the pulmonary artery these valves are opened, and the course of the blood along the tube is uninterrupted; but during the ventricular diastole, when the current of blood along the pulmonary artery is checked and partly thrown back by its elastic walls, these valves become immediately expanded, and effectually close the entrance of the tube. When the valves are closed, the lunated portions of each are brought into contact with one another by their opposed surfaces, the three corpora Arantii filling up the small triangular space that would be otherwise left by the approximation of the three semilunar valves.

Between the semilunar valves and the commencement of the pulmonary artery are three pouches or dilatations, one behind each valve. These are the *pulmonary sinuses of Valsalva*. Similar sinuses exist between the semilunar valves and the commencement of the aorta; they are larger than the pulmonary sinuses. The blood, in its regurgitation toward the heart, finds its way into these sinuses, and so shuts down the valve-flaps.

In order to examine the interior of the left auricle, make an incision on the posterior surface of the auricle from the pulmonary veins on one side to those on the other, the incision being carried a little way into the vessels. Make another incision from the middle of the horizontal one to the appendix.

The *Left Ventricle* (ventriculus sinister) is longer and more conical in shape than the right ventricle, and on transverse section its cavity presents an oval or nearly circular outline. It forms a small part of the anterior surface of the heart and a considerable part of its posterior surface. It also forms the apex of the heart by its projection beyond the right ventricle. Its walls are much thicker than those of the right side, the proportion being as 3 to 1. They are thickest opposite the widest part of the ventricle, becoming gradually thinner toward the base, and also toward the apex, which is the thinnest part.

The following parts present themselves for examination:

1. **Openings**
   - Auriculo-ventricular.
   - Aortic.
   - Chordae tendineae.

2. **Valves**
   - Mitral.
   - Semilunar.
   - Columnae carneae.

The left auriculo-ventricular opening or the mitral orifice (ostium venosum ventriculi sinistri) is placed below and to the left of the aortic orifice. It is a little

---

1 The pulmonary semilunar valves have been found to be two in number instead of three (Dr. Hand, of St. Paul, Minn., in North Western Med. and Surg. Journ., July, 1873), and the same variety is more frequently noticed in the aortic semilunar valves.—Ed. of 15th English edition.
smaller than the corresponding aperture of the opposite side, admitting only two fingers; but, like it, is broader in the transverse than in the antero-posterior diameter. Its right, posterior, and left sides are surrounded by a dense horseshoe-shaped fibrous ring (annulus fibrosus sinister). The orifice is guarded by the mitral valves, which are covered with endocardium.

The aortic opening (ostium arteriosum) is a circular aperture, in front and to the right side of the auriculo-ventricular opening, from which it is separated by one of the segments of the mitral valve. Its orifice is guarded by the semilunar valves. The portion of the ventricle immediately below the aortic orifice is often termed the aortic vestibule of Sibson. It possesses fibrous instead of muscular walls, and so does not collapse during the ventricular diastole; it thus gives space for the segments of the aortic valve during its closure.

Fig. 375.—The left auricle and ventricle laid open, the posterior walls of both being removed.

The mitral or bicuspid valve (valvula bicuspidalis) is attached to the circumference of the auriculo-ventricular orifice in the same way that the tricuspid valve is on the opposite side. It is formed by a duplicature of the lining membrane, strengthened by fibrous tissue, and contains a few muscular fibres. It is larger in size, thicker, and altogether stronger than the tricuspid, and consists of two segments of unequal size. The larger segment, the anterior or aortic cusp (cusps anterior), is placed in front and to the right between the auriculo-ventricular and aortic orifices, the smaller, the posterior or marginal cusp (cusps posterior), is placed to the left and behind the opening, close to the wall of the ventricle. Two smaller segments are usually found at the angles of junction of the larger. The mitral valve-flaps are furnished with chordae tendineæ, the mode of attachment of which is precisely similar to those on the right side; but they are thicker, stronger, and less numerous.

The aortic semilunar valves (valvulae semilunares aortae) surround the orifice of the aorta; one is posterior (valvula semilunaris posterior); one right (valvula
semilunaris dextra), and one left (valvula semilunaris sinistra): they are similar in structure and in their mode of attachment to those of the pulmonary artery. They are, however, larger, thicker, and stronger than those of the right side; the lunulae are more distinct and the corpora Arantii larger and more prominent. Opposite each segment the wall of the aorta presents a slight dilatation or bulging, the sinus of Valsalva.

The columnae carneae admit of a subdivision into three sets, like those upon the right side; but they are smaller, more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall. Those attached by one extremity only, the musculi papillares, are two in number, being connected

one to the anterior, the other to the posterior wall; they are of large size, and terminate by free rounded extremities, from which the chordae tendineae arise.

The septum between the two ventricles (septum ventriculorum) is thick and muscular, especially below (Fig. 376). At its upper part it suddenly tapers off, becomes destitute of muscular fibres, and consists only of fibrous tissue, covered by two layers of endocardium; and on the right side also covered, during diastole, by one of the flaps of the tricuspid valve. This upper portion is termed the undefended or membranous part of the septum (septum membranaceum ventriculorum), and is continued upward and forms the septum between the aortic vestibule and the right auricle. It is derived from the lower part of the aortic septum of the foetus, and an abnormal communication may exist at this part, owing to defective development of this septum.

---

**Fig. 376.**—Section of the heart, showing the interventricular septum.
Structure of the Heart.—The heart is a hollow muscular organ and its walls are divisible into three layers: the endocardium, myocardium, and visceral layer of the pericardium (page 560).

The endocardium is the lining membrane of the heart. It is composed of endothelial cells resting upon a connective-tissue membrane which contains unstriated muscle cells and elastic tissue. This connective-tissue membrane of the endocardium is attached to the myocardium by loose elastic tissue. The endothelial layer of the endocardium is continuous with the endothelial coat of the blood-vessels. The endocardium is more opaque on the left than on the right side of the heart, thicker in the auricles than in the ventricles, and thickest in the left auricle. It is thin on the musculi pectinati and on the columnæ carneæ, but thicker on the smooth parts of the auricular and ventricular walls and on the tips of the musculi papillares.

The fibrous rings (annuli fibrosi) surround the auriculo-ventricular and arterial orifices; they are stronger upon the left than on the right side of the heart. The auriculo-ventricular rings serve for the attachment of the muscular fibres of the auricles and ventricles, and also for the mitral and tricuspid valves; the ring on the left side is closely connected by its right margin with the aortic arterial ring. Between these and the right auriculo-ventricular ring is a mass of fibrous tissue, and in some of the larger animals, as the ox and elephant, a nodule of bone, the os cordis.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, within which the middle coat of the artery (which presents three convex semicircular segments) is firmly fixed, the attachment of the artery to its fibrous ring being strengthened by the thin cellular coat and serous membrane externally and by the endocardium within. It is opposite the margins of these semicircular notches, in the arterial rings, that the endocardium by its reduplication forms the semilunar valves, the fibrous structure of the ring being continued into each of the segments of the valve at this part. The middle coat of the artery in this situation is thin, and the sides of the vessel are dilated to form the sinuses of Valsalva.

The myocardium is composed of muscle fibres which differ from ordinary striated muscle fibres, and are called cardiac fibres. Between individual fibres and between bundles of fibres is connective tissue carrying capillaries.
The **Muscular Structure** of the heart consists of bands of fibres which present an exceedingly intricate interlacement. They are of a deep red color and marked with transverse striae.

The muscular fibres of the heart admit of a subdivision into two groups, those of the auricles and those of the ventricles, which are quite independent of one another.

**Fibres of the Auricles** (Fig. 378).—These are disposed in two layers—a superficial layer common to both cavities, and a deep layer proper to each. The **superficial fibres** are more distinct on the anterior surface of the auricles, across the bases of which they run in a transverse direction, forming a thin but incomplete layer. Some of these fibres pass into the septum atriorum. The **internal or deep fibres** proper to each auricle consist of two sets, looped and annular fibres. The **looped fibres** pass upward over each auricle, being attached by two extremities to the corresponding auriculo-ventricular rings in front and behind. The **annular fibres** surround the whole extent of the auricular appendices, and are continued upon the walls of the vena cavae and coronary sinus on the right side, and upon the pulmonary veins on the left side, at their connection with the heart. In the appendices they interlace with the longitudinal fibres.

![Fig. 378.—The arrangement of the muscles of the auricles. (Poirier and Charpy.)](image)

**Fibres of the Ventricle**s.—These are arranged in an exceedingly complex manner, and the accounts given by various anatomists differ considerably. This is probably due partly to the fact that the various layers of muscular fibres of which the heart is said to be composed are not independent, but their fibres are interlaced to a considerable extent, and therefore any separation into layers must be to a great extent artificial; and also partly to the fact, pointed out by Henle, that there are varieties in the arrangement due to individual differences. If the epicardium and the subjacent fat are removed from a heart which has been subjected to prolonged boiling, so as to dissolve the connective tissues, the superficial fibres of the ventricles will be exposed. They will be seen to commence at the base of the heart, where they are attached to the tendinous rings around the orifices, and to pass obliquely downward toward the apex, with a direction from right to left. At the apex the fibres turn suddenly inward into the interior of the ventricle, forming what is called the **vortex** (Fig. 379). On the back of the heart it will be seen that the fibres pass continuously from one ventricle to the other over the interventricular groove; and the same thing will be noticed on the front of the heart at the upper and lower end of the anterior interventricular groove, but in the middle portion of this groove the fibres passing from one ventricle to the other are inter-
rupted by fibres emerging from the septum along the groove; many of the superficial fibres pass in also at this groove to the septum. The vortex is produced, as stated above, by the sudden turning inward of the superficial fibres in a peculiar spiral manner into the deepest portion of the wall of the ventricle. Those fibres which descended on the posterior surface of the heart enter the left ventricle at the vortex, and, ascending, form the posterior part of the inner layer of muscular fibres lining this cavity and the right (posterior) musculus papillaris; those fibres which descend on the front of the heart to reach the apex also pass, at the vortex, into the interior of the ventricle, where they form the remainder of the innermost layer of the ventricle and the left (anterior) musculus papillaris. The fibres forming the inner layer of the wall of the ventricle ascend to be attached to the fibrous rings around the orifces.

By dissection these superficial fibres may be removed as a thin stratum, and it will then be found that the ventricles are made up of oblique fibres (Fig. 380), super-

![Fig. 379.—The muscular arrangement of the apex of the heart. (Poirier and Charpy.)](image)

![Fig. 380.—The muscular arrangement of the ventricle. (Poirier and Charpy.)](image)

imposed in layers one on the top of another, and assuming gradually a less oblique direction as they pass to the middle of the thickness of the ventricular wall, so that
in the centre of the wall the fibres are transverse. Internal to this central transverse layer the fibres become oblique again, but in the opposite direction to the external ones. This division into distinct layers is, however, to a great extent artificial, as the fibres pass across from one layer to another, and have therefore to be divided in the dissection, and the change in the direction of the fibres is very gradual. These oblique fibres commence above at the fibrous rings at the base of the heart, and, descending toward the apex, they enter the septum near its lower end. In the septum the fibres which form the left ventricle may be traced in three directions: 1. Some pass upward to be attached to the central mass of fibrous tissue. 2. Others pass through the septum to become continuous with the fibres of the right ventricle. 3. The remainder pass through the septum to encircle the ventricle as annular fibres. Of the fibres of the right ventricle, some on entering the septum pass upward to be attached to the central mass of fibrous tissue; some, entering the septum from behind, pass forward to become continuous with the fibres on the anterior surface of the left ventricle; and others, entering in front, pass backward to join the fibres on the posterior wall of the left ventricle. The septum therefore consists of three varieties of fibres—viz., annular fibres, special to the left ventricle; ascending fibres, derived from both ventricles and ascending through the septum to the central fibro-cartilage; and decussating fibres, derived from the anterior wall of one ventricle and passing to the posterior wall of the other ventricle, or from the posterior wall of the right ventricle and passing to the anterior wall of the left. In addition to these fibres there are a considerable number which appear to encircle both ventricles and which pass across the septum without turning into it.

**Vessels and Nerves.**—The arteries supplying the heart are the right and left coronary from the aorta. Branches from the coronary vessels supply the muscular structure, the subendocardial, and the subepicardial tissue. There are no vessels in the endocardium. The valves contain no vessels unless they contain muscle, in which case minute vessels enter them. There are numerous capillary networks about the muscular fibres.

The veins accompany the arteries. They are: the anterior or great, the posterior, the left, and the anterior cardiac veins, the right or small, and the left or great, coronary sinuses. The coronary sinus receives most of the veins of the heart and empties into the right auricle. Some few small veins open directly into the right and left auricles and into the ventricles. They are the venæ minimaæ cordis. The oblique vein of the left auricle is known as the oblique vein of Marshall.

The lymphatics are arranged in two networks: one in the muscle beneath the endocardium, another in the muscle beneath the epicardium. The deep empties into the superficial network, the anterior collecting trunks from the subepicardial network pass to the tracheo-bronchial glands. The posterior collecting trunk terminates in the same group of glands.¹

The nerves are derived from the superficial and deep cardiac plexuses, and from these plexuses obtain fibres of the pneumogastric, spinal accessory, and sympathetic. The superficial cardiac plexus lies under the arch of the aorta. The deep cardiac plexus is in front of the tracheal bifurcation. The nerves from the plexuses are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia.

**Surface Form.**—In order to show the extent of the heart in relation to the front of the chest, draw a line from the lower border of the second left costal cartilage, one inch from the sternum, to the upper border of the third right costal cartilage, half an inch from the sternum. This represents the base-line or upper limit of the organ. Take a point an inch and a half below and three-quarters of an inch internal to the left nipple—that is, about three and a half inches to the left of the median line of the body. This represents the apex of the heart. Draw a line

¹ The Lymphatics. By Polier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
from this apex-point, with a slight convexity downward, to the junction of the seventh right costal cartilage to the sternum. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base-line— with the right extremity of this line—that is, to the seventh right chondro-sternal joint—with a slight curve outward, so that it projects about an inch and a half from the middle line of the sternum. Lastly, join the left extremity of the base-line and the apex-point by a line curved slightly to the left.

The position of the various orifices is as follows—viz., the pulmonary orifice is situated in the upper angle formed by the articulation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the articulation of the third left costal cartilage to this bone. The left auriculo-ventricular opening is behind the sternum, rather to the left of the median line, and opposite the fourth costal cartilages. The right auriculo-ventricular opening is a little lower, opposite the fourth interspace and in the middle line of the body (Fig. 306).

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the area of superficial cardiac dulness; the latter as the area of deep cardiac dulness. The area of superficial cardiac dulness is included between a line drawn from the centre of the sternum, on a level with the fourth costal cartilages, to the apex of the heart and a line drawn from the same point down the lower third of the middle line of the sternum. Below, this area merges into the dulness which corresponds to the liver. Dr. McClellan states that the area of superficial cardiac dulness may be mapped out "by drawing a line from the middle of the sternum opposite the fourth left costal cartilage to the point of junction of the fifth rib and its cartilage, and from this point horizontally back to the mid-sternal line."

Surgical Anatomy.—Wounds of the heart are often immediately fatal, but not necessarily so. They may be non-penetrating, when death may occur from hemorrhage, if one of the coronary vessels has been wounded, or subsequently from pericarditis; or, on the other hand, the patient may recover. Even a penetrating wound is not necessarily fatal, if the wound is a small one. An attempt should be made to save the patient by means of a surgical operation. A trap-door flap comprising the whole thickness of the thoracic wall should be made. The hinges of the trap-door are the rib cartilages. The pericardium is exposed and opened freely, clots are removed, the wound in the heart is sought for, and when discovered is sutured. In a penetrating wound the sutures include the whole thickness of the heart, except the endocardium. Interrupted sutures should be used, and each one had better be tied during diastole. A number of successful operations of this character have been performed.

Peculiarities in the Vascular System of the Fœtus (Fig. 382).

The chief peculiarities in the heart of the fœtus are the direct communication between the two auricles through the foramen ovale, and the large size of the Eustachian valve. There are also several minor peculiarities. Thus, the position of the heart is vertical until the fourth month, when it commences to assume an oblique direction. Its size is also very considerable as compared with the body, the proportion at the second month being 1 to 50; at birth it is as 1 to 120; whilst in the adult the average is about 1 to 160. At an early period of fœtal life the auricular portion of the heart is larger than the ventricular, the right auricle being more capacious than the left; but toward birth the ventricular portion becomes the larger. The thickness of both ventricles is at first about equal, but toward birth the left becomes much the thicker of the two.

The foramen ovale (Fig. 381) is situated at the lower and back part of the septum atriorum, forming a communication between the auricles. It remains as a free oval opening until the middle period of fœtal life. About this period a fold grows up from the posterior wall of the auricle to the left of the foramen ovale, and advances over the opening so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, and not in the opposite direction.

The Eustachian valve (Fig. 381) is directed upward on the left side of the opening of the inferior vena cava, and serves to direct the blood from this vessel through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fœtus are the communication between the pulmonary artery and the descending aorta by means of the ductus
arteriosus, and the communication between the internal iliac arteries and the placenta by means of the umbilical arteries.

The Ductus Arteriosus (Fig. 382).—The ductus arteriosus is a short tube, about half an inch in length at birth, and of the diameter of a goose-quill. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta just below the origin of the left subclavian artery, and so conducts the chief part of the blood from the right ventricle into this vessel. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord (ligamentum arteriosum), which is all that remains of the ductus arteriosus in later life, will be found to be attached to the root of that vessel.

The Umbilical Arteries.—The umbilical or hypogastric arteries arise from the internal iliacs, in addition to the branches given off from those vessels in the adult. Ascending along the sides of the bladder to its apex, they pass out of the abdomen at the umbilicus and are continued along the umbilical cord to the placenta, coiling round the umbilical vein. They carry to the placenta the blood which has circulated in the system of the foetus.

![Diagram of the heart](image)

**Fig. 381.**—The right auricle of a foetal heart (eighth month). Enlarged. (Spalteholz.)

The peculiarity in the venous system of the foetus is the communication established between the placenta and the liver and portal vein through the umbilical vein, and the inferior vena cava through the ductus venosus.

Foetal Circulation.—The blood destined for the nutrition of the foetus is returned from the placenta to the foetus by the umbilical vein. This vein enters the abdomen at the umbilicus, and passes upward along the free margin of the suspensory ligament of the liver to the under surface of that organ, where it gives off two or three branches to the left lobe, one of which is of large size, and others to the lobus quadratus and lobulus Spigelii. At the transverse fissure it divides into two branches: of these, the larger is joined by the portal vein and enters the right lobe; the smaller branch continues outward, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein reaches the inferior vena cava in three different ways: the greater quantity circulates through the liver with the portal venous blood before entering the vena cava.
cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior cava by the hepatic veins; the smaller quantity passes directly into the vena cava by the junction of the ductus venosus with the left hepatic vein.

In the inferior cava the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and wall of the abdomen. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it becomes mixed with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle, and from the left ventricle into
the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the tributaries of the superior vena cava to the right auricle, where it becomes mixed with a small portion of the blood from the inferior cava. From the right auricle it descends over the Eustachian valve into the right ventricle, and from the right ventricle passes into the pulmonary artery. The lungs of the foetus being inactive, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and is returned by the pulmonary veins to the left auricle; the greater part passes through the ductus arteriosus into the commencement of the descending aorta, where it becomes mixed with a small quantity of blood transmitted by the left ventricle into the aorta. Through this vessel it descends to supply the lower extremities and viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the foetus it will be seen—

1. That the placenta serves the purposes of nutrition and excretion, receiving the impure blood from the foetus, and returning it charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver before entering the inferior cava; hence the large size of this organ, especially at an early period of foetal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior cava being guided by the Eustachian valve into the left auricle, whilst that in the superior cava descends into the right ventricle. At an early period of the foetal life it is highly probable that the two streams are quite distinct, for the inferior cava opens almost directly into the left auricle, and the Eustachian valve would exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems probable that some mixture of the two streams must take place.

4. The pure blood carried from the placenta to the foetus by the umbilical vein, mixed with the blood from the portal vein and inferior cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities; hence the large size and perfect development of those parts at birth.

5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and upper limbs, together with a small quantity from the left ventricle, is distributed to the lower extremities; hence the small size and imperfect development of these parts at birth.

Changes in the Vascular System at Birth.

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, which now perform their office as respiratory organs, and at the same time the placental circulation is cut off. Almost immediately after birth the foramen ovale is closed by the valvular edge being pressed against the annulus ovalis, the pressure being due to respiration, which increases the pressure in the left auricle. The structures fuse, and closure is complete by about the tenth day after birth. The valvular fold above mentioned becomes adherent to the margins of the foramen for the greater part of its circumference, but above a slit-like opening is left between the two auricles which sometimes remains persistent.
The ductus arteriosus begins to contract immediately after respiration is established, becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord which serves to connect the left pulmonary artery to the descending aorta. When respiration begins, the caval opening of the diaphragm being fixed and the balance of the muscle rising and falling, the ductus arteriosus is compressed by the muscular structures which pass from the diaphragm to the pericardium, is narrowed, and is finally obliterated (Forbes).

Of the umbilical or hypogastric arteries, the portion continued on to the bladder from the trunk of the corresponding internal iliac remains pervious as the superior vesical artery, and the part extending from the side of the bladder to the umbilicus becomes obliterated between the second and fifth days after birth, and projects as a fibrous cord toward the abdominal cavity, carrying on it a fold of peritoneum and separating two of the fossae of the peritoneum spoken of in the section on the surgical anatomy of direct inguinal hernia.

The umbilical vein and the ductus venosus become completely obliterated between the second and fifth days after birth, and ultimately dwindle to fibrous cords, the former becoming the round ligament of the liver, the latter the fibrous cord, which in the adult may be traced along the fissure of the ductus venosus.
THE ARTERIES.

The Arteries are cylindrical tubular vessels which serve to convey blood from both ventricles of the heart to every part of the body. These vessels were named arteries (ἀρτηρία, air; ἄρτηρεια, to contain) from the belief entertained by the ancients that they contained air. To Galen is due the honor of refuting this opinion; he showed that these vessels, though for the most part empty after death, contain blood in the living body.

The distribution of the systemic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle of the heart, the smallest ramifications corresponding to the circumference of the body and the contained organs. The arteries are found in nearly every part of the body, with the exception of the hairs, nails, epidermis, cartilages, and cornea; and the larger trunks usually occupy the most protected situations, running, in a limb, along the flexor side, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as we observe in the coeliac and thyroid axes; or the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs; but the usual division is dichotomous; as, for instance, the aorta dividing into the two common iliacs, and the common carotid into the external and internal carotids.

The branches of arteries arise at very variable angles: some, as the superior intercostal arteries from the aorta, arise at an obtuse angle; others, as the lumbar arteries, at a right angle; or, as the spermatic, at an acute angle. An artery from below the point at which a branch is given off is smaller in size than before. It retains a uniform diameter until a second branch is derived from it. A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined area of all the arterial branches greatly exceeds the area of the aorta; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, the base to the capillary system.

The arteries, in their distribution, communicate with one another, forming what is called an anastomosis (ἀνάστομοσις, between; στόμα, mouth) or inosculated (Fig. 383); and this communication is very free between the larger as well as between the

(583)
smaller branches. An anastomosis between trunks of equal size is found where great activity of the circulation is requisite, as at the base of the brain; here the two vertebral arteries unite to form the basilar, and the two internal carotid arteries are connected by a short communicating trunk; it is also found in the abdomen, the intestinal arteries having very ample anastomoses between their larger branches. In the limbs the anastomoses are most numerous and of largest size around the joints, the branches of an artery above inosculating with branches from the vessels below; these anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a collateral circulation is established after the application of a ligature to an artery for the cure of aneurism. The smaller branches of arteries anastomose more frequently than the larger, and between the smallest twigs these inosculations become so numerous as to constitute a close network that pervades nearly every tissue of the body.

A terminal artery is one which forms no anastomoses. Such vessels are found in the brain, spleen, kidneys, lungs, and mesentery.

Throughout the body generally the larger arterial branches pursue a perfectly straight course, but in certain situations they are tortuous; thus the facial arteries in their course over the face, and the arteries of the lips, are extremely tortuous in their course, to accommodate themselves to the movements of the parts. The uterine arteries are also tortuous, to accommodate themselves to the increase of size which the organ undergoes during pregnancy. Again, the internal carotid and vertebral arteries, previous to their entering the cavity of the skull, describe a series of curves, which are evidently intended to diminish the velocity of the current of blood by increasing the extent of surface over which it moves and adding to the resistance which is produced by friction.

The arteries are dense in structure, of considerable strength, highly elastic, and, when divided, they preserve, although empty, their cylindrical form.

**Histology of the Capillaries and Arteries. The Capillaries** (Fig. 386).—The capillaries are very small endothelial tubes which connect the venous system with the arterial system. In diameter they vary from $\frac{1}{10}$ to $\frac{1}{6}$ of an inch. The nucleated endothelial cells which constitute the wall of a capillary are flat, irregular in outline, and are united by a cement material. Small openings (stomata) are frequently noted between these cells, but they are probably artifacts and do not exist during life.

The capillaries anastomose and form vast networks. When an artery is about to become a capillary the muscular coat disappears. The endothelial coat which constitutes the capillaries extends as a system of endothelial tubes throughout the entire blood-vascular system. The heart is a great muscular thickening around a portion of the system of endothelial tubes. An artery consists of an endothelial

---

**Fig. 384.** Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. Magnified about 350 diameters. A, artery, showing the nucleated endothelium c, which lines it; the vessel being constricted, the endothelial cells appear very thick. Underneath the endothelium is the wavy elastic intima. The chief part of the wall of the vessel is occupied by the circular muscle-coat m; the staff-shaped nuclei of the muscle-cells are well seen. Outside this is a, part of the adventitia. This is composed of bundles of connective-tissue fibres, shown in section, with the nuclei of the connective-tissue corpuscles. The adventitia gradually merges into the surrounding connective-tissue. V, vein, showing a thin endothelial membrane e, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media m. This latter is composed of a few circular unstriped muscle-cells; a, the adventitia, similar in structure to that of an artery. (Klein and Noble Smith.)
tube covered by certain accessory coats. The wall of an artery diminishes greatly in thickness (Fig. 387) and is found to be composed of endothelial cells and scattered unstriated muscle-fibres, covered merely by thin connective tissue or elastic-tissue sheath (adventitia capillaris). Such a structure is known as an arteriole or a precapillary artery. By the loss of its thin sheath of connective or elastic tissue it becomes a capillary. A capillary takes on a thin sheath and becomes a venule or precapillary vein. Nerves do not terminate in capillaries, but networks of nerve-filaments often encompass these small vessels.

An artery consists of an internal coat or tunica intima, a middle coat or tunica media, and an external coat or tunica adventitia (Figs. 384 and 385).

The Inner Coat (tunica intima) consists of endothelial cells and yellow elastic tissue. In some cases the elastic fibres are arranged longitudinally, but, as a rule, they form a distinct fenestrated membrane known as the fenestrated membrane of Henle, or the internal elastic coat. In medium-sized vessels the elastic layer of the intima is separated from the endothelial layer by a layer of connective tissue. In the large arteries the interposed layer of connective tissue is thicker and contains elastic fibres.

The Middle Coat (tunica media) consists of muscle, elastic tissue, and white fibrous tissue, and it is often called the elastomuscular coat. The arterioles contain scattered unstriated muscle fibres. In the small arteries they constitute a thin but definite coat. In larger arteries the muscular coat is much thicker. The muscle is unstriated and the fibres are arranged circularly, and in the larger vessels form layers which are separated by elastic fibres. Here and there longitudinally-disposed muscle-fibres exist. The larger the artery the greater is the amount of elastic tissue existing in the middle coat. In the aorta and in some of the very large arteries the amount of elastic tissue exceeds the amount of

---

**Fig. 385.**—Section of a medium-sized artery. (After Grünstein.)
muscular tissue. "In the first part of the aorta, in the pulmonary artery and in the arteries of the retina, the muscular fibres are entirely replaced by elastic tissue."\(^1\) The arteries within the skull have no elastic tissue in the media, although they have some in the adventitia.

The External Coat (tunica adventitia) is called the fibrous coat. It contains fibrous connective tissue, elastic tissues, and in some arteries fibres of unstriated muscle arranged longitudinally. The circular elastic membrane which separates the outer coat from the middle coat is known as the external elastic membrane.

**Blood-vessels of the Blood-vessel Wall.**—Many small blood-vessels course in the external and middle coats of arteries of large and of moderate size. They are mostly in the adventitia. They may arise from the vessel to which they are distributed or take origin from an adjacent vessel. These small arteries are called the vasa vasorum. The blood is returned from the walls of the vessels by small veins.

**Lymphatics.**—Distinct lymphatic vessels may exist in the adventitia, but are not found in either of the other coats. Lymph-capillaries often surround small blood-vessels or a small blood-vessel may lie in a perivascular lymph-space.

**Nerves.**—Arteries are supplied with nerves, medullated and non-medullated. A network of nerve-fibres may surround a vessel and usually capillaries are so surrounded. In the arteries a network of nerves exists in the media. These nerves supply the muscle-fibres and are called vasomotor nerves.

The Arterial Sheath (vagina vasis) surrounds the artery. It is composed of connective tissue and is attached to the vessel at numerous points by fibrous tissue.

\(^1\) D. J. Cunningham. Text-book of Anatomy.
PULMONARY ARTERY (A. PULMONALIS) (Fig. 389, 391).

In the description of the arteries we shall first consider the efferent trunk of the pulmonic circulation, the pulmonary artery, and then the efferent trunk of the systemic circulation, the aorta and its branches.

The pulmonary artery conveys the venous blood from the right side of the heart to the lungs. It is a short, wide vessel, about 2 inches in length and 1 1/2 inches (30 mm.) in diameter, arising from the left side of the base (conus arteriosus) of the right ventricle, in front of the aorta. It extends obliquely upward and backward, passing at first in front of and then to the left of the ascending aorta, as far as the under surface of the arch, where it divides, about on a level with the intervertebral substance between the fifth and sixth dorsal vertebrae, into two branches of nearly equal size, the right and left pulmonary arteries.

The Right Pulmonary Artery (ramus dexter a. pulmonalis), longer and larger than the left, runs horizontally outward to the root of the right lung, where it divides into two branches, of which the lower and larger supplies the middle and lower lobes; the upper and smaller is distributed to the upper lobe. It has in front of it the ascending aorta, the superior vena cava, and the right phrenic nerve. It has behind it the right bronchus. Above it is the transverse portion of the arch of the aorta. Below it is the right auricle.

The Left Pulmonary Artery (ramus sinister a. pulmonalis), shorter and somewhat smaller than the right, passes horizontally to the root of the left lung, where it divides into two branches for the two lobes. In front of it and below it are the pulmonary veins of the left side. Behind are the descending aorta and the left bronchus. Above it are the arch of the aorta, the left recurrent laryngeal nerve, and the ductus arteriosus. The left bronchus in a portion of its course lies below as well as behind.

Relations.—The whole of the vessel is contained, together with the ascending aorta, in the pericardium. It is enclosed with the aorta in a single tube of the serous pericardium, which is continued upward upon them from the base of the heart and connects them together. The fibrous layer of the pericardium becomes gradually lost upon the external coats of its two branches. In front, the pulmonary artery is separated from the anterior extremity of the second left intercostal space by the pleura and left lung, in addition to the pericardium; it rests at first upon the ascending aorta, and higher up lies in front of the left auricle on a plane posterior to the ascending aorta. On each side of its origin is the appendix of the corresponding auricle and a coronary artery, the left coronary artery passing, in the first part of its course, behind the vessel.

The root of the left pulmonary artery is connected to the under surface of the arch of the aorta by a short fibrous cord, the ligamentum arteriosum; this is the remains of a vessel peculiar to foetal life, the ductus arteriosus.

The terminal branches of the pulmonary artery will be described with the anatomy of the lung.

THE AORTA (Figs. 388, 389, 390, 391).

The aorta or arteria magna (ἀορτή) is the main trunk of a series of vessels which convey the oxygenated blood to the tissues of the body for their nutrition. This vessel commences at the upper part of the left ventricle, where it is about one and one-eighth inches in diameter, and, after ascending for a short distance, arches backward and to the left side, over the root of the left lung, then descends within the thorax on the left side of the vertebral column, passes through the aortic opening in the Diaphragm, and, entering the abdominal cavity, terminates, consider-
ably diminished in size (about seven-tenths of an inch in diameter), opposite the lower border of the fourth lumbar vertebra, where it divides into the right and left common iliac arteries. Hence it is divided into the ascending aorta, the arch of the aorta, and the descending aorta, which last is again divided into the thoracic aorta and the abdominal aorta, from the position of these parts.

THE ASCENDING AORTA (AORTA ASCENDENS).

The ascending aorta is about two inches in length. It commences at the upper part of the left ventricle, on a level with the lower border of the third costal cartilage, behind the left half of the sternum; it passes obliquely upward, forward, and to the right, in the direction of the heart's axis, as high as the upper border of the second right costal cartilage, describing a slight curve in its course, and being situated, when distended, about a quarter of an inch behind the posterior surface of the sternum. A little above its commencement it is somewhat enlarged (bulbus aortae), and presents three small dilatations, one of which is anterior, two of which are posterior, which are called the sinuses of Valsalva (sinus aortae). Opposite to the sinuses are attached the three semilunar valves (Fig. 376),
which serve the purpose of preventing any regurgitation of blood into the cavity of the ventricle. These valves are placed one in front and two behind. At the union of the ascending with the transverse part of the aorta the calibre of the vessel is increased, owing to a bulging outward of its right wall. This dilatation is termed the great sinus of the aorta. A section of the aorta opposite this part has a somewhat oval figure; but below the attachment of the valves it is circular. This portion of the aorta is contained in the cavity of the pericardium, and, together with the pulmonary artery, is invested in a tube of serous membrane, continued on to them from the surface of the heart.

**Fig. 389.**—The arch of the aorta and its branches.

**Fig. 390.**—Plan of the branches.

**Relations.**—The ascending aorta is covered at its commencement by the trunk of the pulmonary artery and the right auricular appendix, and, higher up, is separated from the sternum by the pericardium, the right pleura, and anterior margin of the right lung; some loose areolar tissue, and the remains of the thymus gland; behind, it rests upon the right pulmonary artery, left auricle, and the right bronchus. On the right side it is in relation with the superior vena cava and right auricle; on the left side, with the pulmonary artery.
Plan of the Relations of the Ascending Aorta.

Behind.
- Right pulmonary artery.
- Left auricle.
- Right bronchus.

Branches—The only branches of the ascending aorta are the coronary arteries. They supply the heart, and are two in number, right and left, arising near the commencement of the aorta, immediately above the free margin of the semilunar valves.

The Coronary Arteries (Fig. 389).

The Right Coronary Artery (a. coronaria [cordis] dextra), about the size of a crow’s quill, arises from the anterior sinus of Valsalva. It passes forward between the pulmonary artery and the right auricular appendix, then runs obliquely to the right side, in the groove between the right auricle and ventricle, and, curving around the right border of the heart, runs to the left along its posterior surface as far as the posterior interventricular groove, where it divides into two branches, one of which, the transverse, continues onward in the groove between the left auricle and ventricle, and anastomoses with the left coronary; the other, the descending (ramus descendens posterior a. coronaria [cordis] dextra), courses along the posterior interventricular furrow, supplying branches to both ventricles and to the septum, and anastomosing at the apex of the heart with the descending branches of the left coronary. This vessel sends a large branch, the marginal, along the thin margin of the right ventricle to the apex, which in its course gives off numerous small branches to the anterior and posterior surfaces of the ventricle. It also gives off a branch, the infundibular, which ramifies over the front part of the conus arteriosus of the right ventricle.

The Left Coronary Artery (a. coronaria [cordis] sinistra), larger than the former, arises from the left posterior sinus of Valsalva; it passes forward between the pulmonary artery and the left auricular appendix, and divides into two branches. Of these, one, the transverse, passes transversely outward in the left auriculo-ventricular groove, and winds around the left border of the heart to its posterior surface, where it anastomoses with the transverse branch of the right coronary; the other, the descending (ramus descendens anterior a. coronaria [cordis] sinistra), passes along the anterior interventricular groove to the apex of the heart, where it anastomoses with the descending branches of the right coronary. The left coronary supplies the left auricle and its appendix, gives branches to both ventricles, and numerous small branches to the pulmonary artery and commencement of the aorta.¹

¹ According to Dr. Samuel West, there is a very free and complete anastomosis between the two coronary arteries (Lancet, June 2, 1883, p. 945). This, however, is not the view generally held by anatomists, for, with the exception of the anastomosis mentioned above in the auriculo-ventricular and interventricular grooves, it is believed that the two arteries only communicate by very small vessels in the substance of the heart.—Ed. of 15th English edition.
Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three, the additional branch being of small size. More rarely there are two additional branches.

THE ARCH OF THE AORTA.

The arch, or transverse aorta (arcus aorta), commences at the upper border of the second chondro-sternal articulation of the right side, and passes at first upward and backward and from right to left, and then from before backward, to the left side of the lower border of the fourth dorsal vertebra behind. Its upper border is usually about an inch below the upper margin of the sternum.

Between the origin of the left subclavian artery and the attachment of the ductus arteriosus the lumen of the foetal aorta is considerably narrowed, forming what is termed the aortic isthmus (isthmus aortae), while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation which His has named the aortic spindle (aortenspindel)—the point of junction of the two parts being marked in the concavity of the arch by an indentation or angle. These conditions persist, to some extent, in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm. (about one-eighth of an inch).

Relations.—Its anterior surface is covered by the pleurae and lungs (much more by the left lung than by the right) and the remains of the thymus gland, and crossed toward the left side by the left pneumogastric and phrenic nerves and superficial cardiac branches of the left sympathetic and vagus, and by the left superior intercostal vein. Its posterior surface lies on the trachea, just above its bifurcation, on the great, or deep, cardiac plexus, the cœsophagus, thoracic duct, and left recurrent laryngeal nerve. Its upper border is in relation with the left innominate vein, and from its upper part are given off the innominate, left common carotid and left subclavian arteries. Its lower border is in relation with the bifurcation of the pulmonary artery, the remains of the ductus arteriosus, which is connected with the left division of that vessel, and the superficial cardiac plexus; the left recurrent laryngeal nerve winds round it from before backward, whilst the left bronchus passes below it.

Left recurrent nerve.

Peculiarities.—The height to which the aorta rises in the chest is usually about an inch below the upper border of the sternum; but it may ascend nearly to the top of that bone. Occasionally it is found an inch and a half, more rarely two or even three inches, below this point.
In Direction.—Sometimes in man, as is normal in birds, the aorta arches over the root of the right instead of the left lung, and passes down on the right side of the spine. In such cases all of the viscera of the thoracic and abdominal cavities are transposed. Less frequently, the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the spine, this peculiarity not being accompanied by any transposition of the viscera.

In Conformation.—The aorta occasionally divides, as in some quadrupeds, into an ascending and descending trunk, the former of which is directed vertically upward, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides soon after its origin into two branches, which soon reunite. In one of these cases the aorta and trachea were found to pass through the interval left by the division of the aorta; this is the normal condition of the vessel in the reptilia.

Surgical Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurism of this part.

It will be remembered that the ascending aorta is continued in the pericardium, just behind the sternum, being crossed at its commencement by the pulmonary artery and right auricular appendix, and having the right pulmonary artery behind, the vena cava on the right side, and the pulmonary artery and left auricle on the left side.

Aneurism of the ascending aorta, in the situation of the sinuses of Valsalva, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses takes place chiefly on the anterior aspect of the vessel. As the aneurismal sac enlarges it may compress any or all of the structures in immediate proximity to it, but chiefly projects toward the right anterior side, and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. In the majority of cases it bursts into the cavity of the pericardium, the patient suddenly drops dead, and, upon a post-mortem examination, the pericardial sac is found full of blood; or it may compress the right auricle, or the pulmonary artery and adjoining part of the right ventricle, and open into one or the other of these parts, or may press upon the superior vena cava.

Aneurism of the ascending aorta, originating above the sinuses, most frequently implicates the right anterior wall of the vessel, where, as has been explained, there exists a normal dilatation, the great sinus of the aorta; this is probably mainly owing to the blood being impelled against this part. The direction of the aneurism is also chiefly toward the right of the median line. It attains a large size and projects forward, it may absorb the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumor on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress or open into the right lung, the trachea, bronchi, or esophagus.
Regarding the *transverse aorta*, the student is reminded that the vessel lies on the trachea, the oesophagus, and thoracic duct; that the recurrent laryngeal nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. An aneurismal tumor, taking origin from the posterior part of the vessel, its most usual site, may press upon the trachea, impede the breathing, or produce cough, hemoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hemorrhage. Again, its pressure on the laryngeal nerves may give rise to symptoms which so accurately resemble those of laryngitis that the operation of tracheotomy has in some cases been resorted to, from the supposition that disease existed in the larynx; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the oesophagus, producing dysphagia; or may burst into the oesophagus, when fatal hemorrhage will occur. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist or in the left temporal artery; or the tumor may present itself at or above the manubrium, generally either in the median line or to the right of the sternum, and may simulate an aneurism of one of the arteries of the neck.

**Branches** (Figs. 389 and 390).—The branches given off from the arch of the aorta are three in number: the *innominate*, the *left common carotid*, and the *left subclavian arteries*.

**Peculiarities.** **Position of the Branches.**—The branches, instead of arising from the highest part of the arch (their usual position), may be moved more to the right, arising from the commencement of the transverse or upper part of the ascending portion; or the distance from one another at their origin may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid toward the innominate artery. The *Number* of the primary branches may be reduced to a single vessel, or more commonly two; the left carotid arising from the innominate artery, or (more rarely) the carotid and subclavian arteries of the left side arising from the innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it was the second or third branch given off instead of the first. Another common form in which there are four primary branches is that in which the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks from the arch may be increased to five or six; in these instances, the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides. In some cases, where six branches have been found, it has been due to a separate origin of the vertebral on both sides.

**Number As Usual, Arrangement Different.**—When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual, the innominate supplying the left side, and the carotid and subclavian (which arise separately) the right side. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch. 1

In some instances other arteries are found to arise from the arch of the aorta. Of these the most common are the bronchial, one or both, and the thyroid ima; but the internal mammary and the inferior thyroid have been seen to arise from this vessel.

**The Innominate Artery (A. Anonyma)** (Figs. 389, 390, 391).

The innominate or *brachio-cephalic* artery is the largest branch given off from the arch of the aorta. It *arises*, on a level with the upper border of the second right costal cartilage, from the commencement of the arch of the aorta in front of the left carotid, and, ascending obliquely to the upper border of the right sterno-clavicular articulation, divides into the right common carotid and right subclavian arteries. This vessel varies from an inch and a half to two inches in length.

**Relations.**—In *front*, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the left innominate and right inferior thyroid veins which cross its root, and sometimes the inferior cervical cardiac branch of the right pneumogastric. *Behind*, it

---

1 The anomalies of the aorta and its branches are minutely described by Krause in Henle's Anatomy (Bruns-wick, 1808), vol. iii. p. 203 et seq. —En. of 15th English edition

38
lies upon the trachea, which it crosses obliquely, and continuing upward it lies in the right pleura. On the right side is the right innominate vein, right pneumogastric nerve, and the pleura; and on the left side, the remains of the thymus gland, the origin of the left carotid artery, the left inferior thyroid vein, and the trachea.

**Branches.**—The innominate usually gives off no branches, but occasionally a small branch, the *thyroidea ima*, is given off from this vessel. It also sometimes gives off a thymic or bronchial branch.

The *Thyroidea Ima* (*a. thyroidea ima*), which is occasionally present, ascends in front of the trachea to the lower part of the thyroid body, which it supplies. It varies greatly in size, and appears to compensate for the deficiency or absence of one of the other thyroid vessels. It occasionally is found to arise from the right common carotid or from the aorta, the subclavian, or internal mammary vessels.

**Plan of the Relations of the Innominate Artery.**

**In front.**
- Sternal.
- Sterno-hyoid and Sterno-thyroid muscles.
- Remains of the thymus gland.
- Left innominate and right inferior thyroid veins.
- Inferior cervical cardiac branch from right pneumogastric nerve.

**Right side.**
- Right innominate vein.
- Right pneumogastric nerve.
- Pleura.

**Innominate Artery.**

**Left side.**
- Remains of thymus.
- Left carotid.
- Left inferior thyroid vein.
- Trachea.
- Pleura.

**Behind.**
- Trachea.
- Right pleura.

**Peculiarities in Point of Division.**—When the bifurcation of the innominate artery varies from the point above mentioned it sometimes ascends a considerable distance above the sternal end of the clavicle; less frequently it divides below it. In the former class of cases its length may exceed two inches, and in the latter be reduced to an inch or less. These are points of considerable interest for the surgeon to remember in connection with the operation of tying this vessel.

**Position.**—When the aorta arches over to the right side, the innominate is directed to the left side of the neck instead of the right.

**Collateral Circulation.**—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligation of the innominate artery, by tying and dividing that artery, after which, he says, “Even coarse injection, impelled into the aorta, passing freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely.” The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while the anastomosis between the superior intercostal of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct course, into the right subclavian: the numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the deep epigastric, from the external iliac, would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the chest.

**Surgical Anatomy.**—The innominate artery has been tied at least thirty times and in six instances, according to Mr. Jacobson, the patient survived. Mott’s patient, however, on whom the operation was first performed, lived nearly four weeks, and Graefe’s more than two months. In 1895 Burrell, of Boston, resected the right sterno-clavicular articulation with the upper end of the sternum and tied the innominate. The patient lived 104 days. The

---

1 Surgical Anatomy of the Head and Neck, p. 62.
ligation was first successfully performed by A. W. Smyth, of New Orleans, in 1864, for subclavian aneurism. The patient died ten years later of the original aneurism, which was reformed by the collaterals. The chief danger of the operation appears to be the frequency of secondary hemorrhage; but in the present day, with the practice of aseptic surgery and our greater knowledge of the use of the ligature, more favorable results may be anticipated. Other causes of death after operation are pleurisy, pericarditis, and suppurative cellulitis. The main obstacles to the operation are, as the student will perceive from his dissection of this vessel, the deep situation of the artery behind and beneath the sternum, and the number of important structures which surround it in every part.

In order to apply a ligature to this vessel, the patient is to be placed upon his back, with the thorax slightly raised, the head bent a little backward, and the shoulder on the side of the aneurism strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision three or more inches long is then made along the anterior border of the Sterno-mastoid muscle, terminating at the sternal end of the clavicle. From this point a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided on a director: the sternal end of the Sterno-mastoid is now brought into view, and, a director being passed beneath it and close to its under surface, so as to avoid any small vessels, it is to be divided; in like manner the clavicular origin is to be divided throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear the Sterno-hyoid and Sterno-thyroid muscles will be exposed, and must be divided, a director being previously passed beneath them. The inferior thyroid veins may come into view, and must be carefully drawn, either upward or downward, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibro-cellular lamina, the right carotid is brought into view, and, being traced downward, the artery innominata is arrived at. The left innominate vein should now be depressed; the right innominate vein, the internal jugular vein, and the pneumogastric nerve drawn to the right side; and a curved aneurism needle may then be passed around the vessel, close to its surface, and in a direction from below upward and inward, care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum. The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac whilst including the vessel in the ligature, should be most carefully borne in mind. After the artery has been secured, the common carotid should be tied about half an inch above its origin, and also the thyroidea ima if the vessel is of any size. The several muscles are united by buried sutures. An easier and safer plan than the above is that employed by Burrell—viz., resection of the right sterno-clavicular articulation and of the upper end of the sternum.

**ARTERIES OF THE HEAD AND NECK.**

The chief artery which supplies the head and neck is the common carotid: it ascends in the neck and divides into two branches: the External Carotid, supplying the superficial parts of the head and face and the greater part of the neck; and the Internal Carotid, supplying to a great extent the parts within the cranial cavity.

**THE COMMON CAROTID ARTERY (A. CAROTIS COMMUNIS) (Figs. 388, 389, 390, 392).**

The common carotid arteries, although occupying a nearly similar position in the neck, differ in position, and, consequently, in their relation at their origin. The right common carotid (*a. carotis communis dextra*) arises from the innominate artery, behind the right sterno-clavicular articulation. The left common carotid (*a. carotis communis sinistra*) arises from the highest part of the arch of the aorta, and is, consequently, longer, and at its origin is contained within the thorax. The course and relations of that portion of the left carotid which intervenes between the arch of the aorta and the left sterno-clavicular articulation will first be described. (See Figs. 388, 389, and 390.)

The left carotid within the thorax ascends obliquely outward from the arch of the aorta to the root of the neck. *In front*, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the left innomi-
nate vein, and the remains of the thymus gland; *behind*, it lies on the trachea, oesophagus, thoracic duct, and the left recurrent laryngeal nerve. *Internally*, it is in relation with the innominate artery, inferior thyroid veins and remains of the thymus gland; *externally*, with the left pneumogastric nerve, left pleura, and left lung. The left subclavian artery is posterior and slightly external to it.

**Plan of the Relations of the Left Common Carotid.**

**Thoracic Portion.**

*In front.*

- Remains of the thymus gland.

*Externally.*

- Left pneumogastric nerve.
- Left pleura and lung.
- Left subclavian artery.

*Behind.*

- Trachea.
- Esophagus.
- Thoracic duct.
- Left recurrent laryngeal nerve.

In the neck the two common carotids resemble each other so closely that one description will apply to both. Each vessel passes obliquely upward from behind the sterno-clavicular articulation to a level with the upper border of the thyroid cartilage, opposite the fourth cervical vertebra, where it divides into the external and internal carotid; these names being derived from the distribution of the arteries to the external parts of the head and face and to the internal parts of the cranium and orbit respectively.

At the lower part of the neck the two common carotid arteries are separated from each other by a small interval, which contains the trachea; but at the upper part, the thyroid body, the larynx and pharynx project forward between the two vessels, and give the appearance of their being placed farther back in this situation. The common carotid artery is contained in a sheath derived from the deep cervical fascia, which also encloses the internal jugular vein and pneumogastric nerve, the vein lying on the outer side of the artery, and the nerve between the artery and vein, on a plane posterior to both. On opening the sheath these three structures are seen to be separated from one another, each being enclosed in a separate fibrous investment.

**Relations.**—At the lower part of the neck the common carotid artery is very deeply seated, being covered by the integument, superficial fascia, Platysma, and deep cervical fascia, the Sterno-mastoid, Sterno-hyoid, and Sterno-thyroid muscles, and by the Omo-hyoid, opposite the cricoid cartilage; but in the upper part of its course, near its termination, it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and inner margin of the Sterno-mastoid, and, when the latter is drawn backward, it is seen to be contained in a triangular space, bounded behind by the Sterno-mastoid, above by the posterior belly of the Digastric, and below by the anterior belly of the Omo-hyoid. This part of the artery is crossed obliquely, from within outward, by the sterno-mastoid artery; it is crossed also by the superior and middle thyroid veins, which terminate in the internal jugular; and, descending on its sheath in front, is seen the descendens hypoglossi nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel from without inward.
Sometimes the descendens hypoglossi is contained within the sheath. The middle thyroid vein crosses the artery about its middle, and the anterior jugular vein below; the latter, however, is separated from the artery by the Sterno-hyoid and Sterno-thyroid muscles. **Behind**, the artery is separated from the transverse processes of the vertebrae by the Longus colli and Rectus capitis anticus major muscles, the sympathetic nerve being interposed between it and the muscles. **The recurrent** laryngeal nerve and inferior thyroid artery cross behind the vessel at its lower part. **Internally**, it is in relation with the trachea and thyroid gland, the latter overlapping it, the inferior thyroid artery and recurrent laryngeal nerve being interposed: higher up, with the larynx and pharynx. On its **outer side** are placed the internal jugular vein and pneumogastric nerve. At the lower part of the neck the internal jugular vein on the right side diverges from the artery, but on the left side it
approaches it, and often overlaps its lower part. This is an important fact to bear in mind during the performance of any operation on the lower part of the left common carotid artery. In this region the relation which the right and left recurrent laryngeal nerves bear to the arteries is not identical. The left recurrent laryngeal nerve lies behind the thoracic portion of the left common carotid artery and internal to the cervical portion of the vessel. The right nerve passes obliquely upward and inward behind the right common carotid to reach its inner side.

**Plan of the Relations of the Common Carotid Artery.**

**Recurrent laryngeal nerve.**

**Peculiarities as to Origin.**—The right common carotid may arise above or below the upper border of the sterno-clavicular articulation. This variation occurs in one out of about eight cases and a half, and the origin is more frequently below than above; or the artery may arise as a separate branch from the arch of the aorta or in conjunction with the left carotid. The left common carotid varies more frequently in its origin than the right. In the majority of abnormal cases it arises with the innominate artery, or, if the innominate artery is absent, the two carotids arise usually by a single trunk. It rarely joins with the left subclavian, except in cases of transposition of the arch.

**Peculiarities as to Point of Division.**—The most important peculiarities of this vessel, in a surgical point of view, relate to its place of division in the neck. In the majority of abnormal cases this occurs higher than usual, the artery dividing into two branches opposite the hyoid bone, or even higher; more rarely it occurs below, opposite the middle of the larynx or the lower border of the cricoid cartilage; and one case is related by Morgagni where the common carotid, only an inch and a half in length, divided at the root of the neck. Very rarely the common carotid ascends in the neck without any subdivision, the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

**Occasional Branches.**—The common carotid usually gives off no branch previous to its bifurcation; but it occasionally gives origin to the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or, more rarely, the vertebral artery.

**Surface Marking.**—The carotid arteries are covered throughout their entire extent by the Stermo-mastoid muscle, but their course does not correspond to the anterior border of the muscle, which passes in a somewhat curved direction from the mastoid process to the sterno-clavicular joint. The course of the artery is indicated more exactly by a line drawn from the sternal end of the clavicle below, to a point midway between the angle of the jaw and the mastoid process above. That portion of the line below the level of the upper border of the thyroid cartilage would represent the course of the vessel.

**Surgical Anatomy.**—The operation of tying the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurism, or in a case of pulsating tumor of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery through the wound above and below the wounded part. If the wound is too small to admit of safe and rapid work it must be enlarged. In cases of aneurism, or where one of
the branches of the common carotid is wounded in an inaccessible situation, it may be judged necessary to tie the trunk. In such cases the whole of the artery is accessible, and any part may be tied except close to either end. When the case is such as to allow of a choice being made, the lower part of the carotid should never be selected as the spot upon which to place a ligature, for not only is the artery in this situation placed very deeply in the neck, but it is covered by three layers of muscles, and, on the left side, in the great majority of cases, the internal jugular vein passes obliquely in front of it. Neither should the upper end be selected, for here the superior thyroid vein and its tributaries would give rise to very considerable difficulty in the application of a ligature. The point most favorable for the operation is that part of the vessel which is at the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position: if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the disease.

Ligation of the Carotid at the Level of the Cricoid Cartilage (Ligation in the Triangle of Elevation).—The triangle of election is bounded posteriorly by the anterior edge of the sternocleido-mastoid; is bounded above by the posterior belly of the digastric; is bounded below by the anterior belly of the omohyoid. In this operation the direction of the vessel and the inner margin of the Sterno-mastoid are the chief guides to its performance. The patient should be placed on his back with the head thrown back and turned slightly to the opposite side: an incision is to be made, three inches long, in the direction of the anterior border of the Sterno-mastoid, so that the centre corresponds to the level of the cricoid cartilage; after dividing the integument, superficial fascia, and Platysma, the deep fascia must be cut through on a director, so as to avoid wounding numerous small veins that are usually found beneath. The head may now be brought forward so as to relax the parts somewhat, and the margins of the wound are held asunder by retractors. The descends hypoglossi nerve may now be exposed, and must be avoided, and, the sheath of the vessel having been raised by forceps, is to be opened to a small extent over the artery at its inner side. The internal jugular vein may present itself alternately distended and relaxed; this should be compressed both above and below, and drawn outward, in order to facilitate the operation. The aneurism needle is passed from the outside, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein or including the vagus nerve. Before the ligature is tied it should be ascertained that nothing but the artery is included in it.

Ligation of the Common Carotid at the Lower Part of the Neck (Ligation in the Triangle of Necessity).—The triangle of necessity is bounded above by the anterior belly of the omohyoid; is bounded behind by the anterior margin of the sternocleido-mastoid; is bounded in front by the mid-line of the neck. This operation is sometimes required in cases of aneurism of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sterno-mastoid muscle, but may be done in some cases, if the aneurism is not of very large size, by an incision along the anterior border of the Sterno-mastoid, extending down to the sterno-clavicular articulation, and by then retracting the muscle. The easiest and best plan, however, is to make an incision two or three inches long down the lower part of the anterior border of the Sterno-mastoid muscle to the sterno-clavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about two inches. This incision is made through the superficial and deep fascia, and the sternal origin of the muscle is exposed. This is to be divided on a director, and turned up, with the superficial structures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the outer border of the Sterno-hyoid muscle exposed. In doing this care must be taken not to wound the anterior jugular vein, which crosses the muscle to reach the external jugular or subclavian vein. The Sterno-hyoid, and with it the Sterno-thyroid, are to be drawn inward by means of a retractor, and the sheath of the vessel is exposed. This must be opened with great care on its inner or tracheal side, so as to avoid the internal jugular vein. This is especially necessary on the left side, where the artery is commonly overlapped by the vein. On the right side there is usually an interval between the artery and the vein, and not the same risk of wounding the latter.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasor's operation for the cure of aneurism of the lower part of the vessel. Brasor's procedure consists in ligaturing the artery on the distal side of the aneurism, and in the case of the common carotid there are no branches given off from the vessel between the aneurism and the site of the ligature; hence the flow of blood through the sac of the aneurism is diminished and cure takes place in the usual way, by the deposit of laminated fibrin.

Collateral Circulation.—After ligation of the common carotid the collateral circulation can be perfectly established, by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied—the
chief communication outside the skull taking place between the superior thyroid from the
external carotid and the inferior thyroid from the subclavian, the profunda cervicis from the
subclavian and the superior intercostal with the arteria princeps cervicis of the occipital;
the vertebral taking the place of the internal carotid within the cranium.

Sir A. Cooper had an opportunity of dissecting, thirteen years after the operation, the case
in which he first successfully tied the common carotid (the second case in which he performed
the operation). The injection, however, does not seem to have been a successful one. It showed
merely that the arteries at the base of the brain (circle of Willis) were much enlarged on the
side of the tied artery, and that the anastomosis between the branches of the external carotid on
the affected side and those of the same artery on the sound side was free, so that the external
carotid was pervious throughout.

The Intercarotid Body (carotid gland, retrocarotid corpuscle) (see the Ductless
Glands).

The External Carotid Artery (A. Carotis Externa) (Figs. 392, 393, 394).

The external carotid artery commences opposite the upper border of the thyroid
cartilage, and, taking a slightly curved course, passes upward and forward, and
then inclines backward to the space between the neck of the condyle of the lower
jaw and the external meatus, where it divides into the superficial temporal and
internal maxillary arteries. It rapidly diminishes in size in its course up the
neck, owing to the number and large size of the branches given off from it. In
the child it is somewhat smaller than the internal carotid, but in the adult the
two vessels are of nearly equal size. At its commencement this artery is more
superficial, and placed nearer the middle line than the internal carotid, and is
contained in the triangular space bounded by the Sterno-mastoid behind, the
anterio belly of the Omo-hyoid below, and the posterior belly of the Digastric
and the Stylo-hyoid above.

Relations.—It is covered by the skin, superficial fascia, Platysma, deep fascia
and anterior margin of the Sterno-mastoid, and is crossed by the hypoglossal nerve,
and by the lingual and facial veins; it is afterward crossed by the Digastric and
Stylo-hyoid muscles, and higher up passes deeply into the substance of the parotid
gland, where it lies beneath the facial nerve and the junction of the temporal and
internal maxillary veins. Internally is the hyoid bone, wall of the pharynx, the
superior laryngeal nerve, and the ramus of the jaw, from which it is separated by
a portion of the parotid gland. Externally, in the lower part of its course, is the
internal carotid artery. Behind it, near its origin, is the superior laryngeal nerve;
and higher up, it is separated from the internal carotid by the Stylo-glossus and
Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and part of the parotid
gland.

Surface Marking.—The position of the external carotid artery may be marked out with sufficient accuracy by a line drawn from the front of the meatus of the external ear to the side of the cricoid cartilage, slightly arching the line forward.

Surgical Anatomy.—The application of a ligature to the external carotid may be required in case of wounds of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumor of the scalp or face. The operation has not received the attention which it deserves, owing to the fear which surgeons have entertained of secondary hemorrhage, on account of the number of branches given off from the vessel. This fear, however, has been shown by Mr. Cripps not to be well founded. Ligation is often very useful as a means of preventing excessive hemorrhage in operations about the face, jaws, and mouth. It is sometimes employed with the hope of lessening the growth of tumors by cutting off the blood supply, but ligation is useless for this purpose. Ligation of one external carotid artery arrests the circulation for only a brief period, and within a very few days the circulation is practically freely re-established. This result is seen to be inevitable when we recall the numerous branches of the external carotid, their free anastomoses, and the fact that a very great number of extremely minute vessels in the middle line join the external carotid system of one side to that of the other side. Robert H. M. Dawbarn points out that ligation of both external carotids produces only temporary anemia, for “inside of a week or ten days thereafter the pulse can again be felt in the temporals and facials upon both sides.” Dawbarn points out that even after excision of the external carotids, with separate ligation of each of the eight branches, blood can still reach the nose, tongue, etc., from outside systems by twenty-nine distinct routes. Whereas ligation of even both carotids will not prevent the growth of a malignant tumor, excision of each external carotid, with separate control of its eight branches, will sometimes prove of great value in retarding the progress of a growth. It ” starves ” the growth and may cause it to shrink (Dawbarn’s operation). To tie the external carotid near its origin, below the point where it is crossed by the Diagastric, an incision about three inches in length should be made along the margin of the Sperm- mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The ligature should be applied between the lingual and superior thyroid branches. To tie the vessel above the Diagastric, between it and the parotid gland, an incision should be made, from the lobe of the ear to the great cornu of the os hyoïdes, dividing successfully the skin, Platysma, and fascia. By drawing the Sperm- mastoid outward, the posterior belly of the Diagastric and Stylo-hyoid muscles downward, and separating them from the parotid gland, the vessel will be exposed, and a ligature may be applied to it. The circulation is at once re-established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side and by the anastomosis of its branches with those of the internal carotid, and of the occipital with the branches of the subclavian, etc.

Branches.—The external carotid artery gives off eight branches, which, for convenience of description, may be divided into four sets. (See Fig. 393, Plan of the Branches.)

The student is here reminded that many variations are met with in the number, origin, and course of these branches in different subjects; but the above arrangement is that which is found in the great majority of cases.

The Superior Thyroid Artery (a. thyroidea superior) (Figs. 392, 393, and 356) is the first branch given off from the external carotid, being derived from that vessel just below the great cornu of the hyoid bone. At its commencement it is quite superficial, being covered by the integument, fascia, and Platysma, and is contained

2 The Treatment of Certain Malignant Growths.
in the triangular space bounded by the Sterno-mastoid, Digastric, and Omo-hyoid muscles. After running upward and inward for a short distance, it curves downward and forward, in an arched and tortuous manner, to the upper part of the thyroid gland, passing beneath the Omo-hyoid, Sterno-hyoid, and Sterno-thyroid muscles, and supplying them. It distributes numerous branches to the upper part of the gland, anastomosing with its fellow of the opposite side and with the inferior thyroid arteries. The terminal branches supplying the gland are generally two in number: one, the largest, the anterior branch (ramus anterior), descends at the anterior border of the lateral lobe of the gland, reaches the upper border of the isthmus, and then passes in the substance of the isthmus to the middle line of the neck, where it anastomoses with the corresponding artery of the opposite side: the posterior branch (ramus posterior) descends along the posterior border of the lateral lobe of the gland, the anterior and posterior branches anastomose with each other and with branches of the inferior thyroid, and both of them send branches to the thyroid gland (rami glandulares). Besides the arteries distributed to the muscles by which it is covered and to the substance of the gland, the branches of the superior thyroid are the following:

**Hyoid.**
Superficial Descending Branch (Sterno-mastoid).

**Superior Laryngeal.**
Crico-thyroid.

The **Hyoid or Infra-hyoid** (ramus hyoideus) is a small branch which runs along the lower border of the os hyoides beneath the Thyro-hyoid muscle; after supplying the muscles connected to that bone, it forms an arch, by anastomosing with the vessel of the opposite side.

The **Superficial Descending** or **Sterno-mastoid Branch** (ramus sternocleidomastoideus) runs downward and outward across the sheath of the common carotid artery, and supplies the Sterno-mastoid and neighboring muscles and integument. There is frequently a separate branch from the external carotid distributed to the Sterno-mastoid muscle.

The **Superior Laryngeal** (a. laryngea superior), larger than either of the preceding, accompanies the internal laryngeal nerve, beneath the Thyro-hyoid muscle: it pierces the thyro-hyoid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **Crico-thyroid** (ramus cricothyreoideus) is a small branch which runs transversely across the crico-thyroid membrane, communicating with the artery of the opposite side.

**Arteries of the Thyroid Gland.**—The thyroid gland is supplied by the two superior thyroids from the external carotid; the two inferior thyroids from the subclavian, and sometimes also by the thyroidea ima from the innominate.

The superior thyroid joins the gland at the summit of the upper horn, passes down the posterior surface of the gland toward the inner surface of the upper horn, comes forward to the anterior margin of the inner surface, descends to the isthmus, and on the superior border of the isthmus anastomoses with the artery from the other side. The superior thyroid artery sends numerous branches across the anterior surface of the gland.

The inferior thyroid artery is larger than the superior artery. It passes to the posterior surface of the gland and divides into branches. Some of the branches enter the hilus; others track across the posterior surface of the gland. The inferior thyroid artery is close to the recurrent laryngeal nerve. The artery, as a rule, passes behind the nerve before it divides into branches. It may divide first and then one or two branches may be in front of the nerve. In unusual cases the artery before division is in front of the nerve, or all the branches are in front.\(^1\)

---

\(^1\) Berry. Diseases of the Thyroid Gland.
THE EXTERNAL CAROTID ARTERY

603

The thyreoida ima passes to the lower portion of the gland. Berry points out that the thyroid arteries communicate very freely with each other; only the small branches pass into the interior of the gland; the larger branches "ramify on the surface of the gland, just beneath the capsule."¹

Surgical Anatomy.—The superior thyroid, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hemorrhage. In such cases the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the position of the artery being very superficial, and the only structures of importance covering it being a few small veins. The operation of tying the superior thyroid artery to lessen the size of a bronchocele has been performed in numerous instances with partial or temporary success. When, however, the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is completely re-established, the tumor usually regains its former size, and hence the operation has been given up, especially as better results are obtained by other means. Both thyroid arteries on the same side, and indeed all the four thyroid arteries, have been tied in enlarged thyroid. The superior and inferior thyroid arteries of the involved side are ligated before extirpating a goitrous lobe of the thyroid.

The position of the superficial descending branch is of importance in connection with the operation of ligation of the common carotid artery. It crosses and lies on the sheath of this vessel, and may chance to be wounded in opening the sheath. The position of the crico-thyroid branch should be remembered, as it may prove the source of troublesome hemorrhage during the operation of laryngotomy. In performing the operation of quick laryngotomy the crico-thyroid membrane should be incised transversely in order to avoid this vessel.

The Lingual Artery (a. lingualis) (Figs. 392 and 393) arises from the external carotid between the superior thyroid and facial; it first runs obliquely upward and inward to the great cornu of the hyoid bone; it then curves downward and forward, forming a loop which is crossed by the hypoglossal nerve, and, passing beneath the Digastric and Stylo-hyoid muscles, it runs horizontally forward, beneath the Hyo-glossus, and finally, ascending almost perpendicularly to the tongue, turns forward on its under surface as far as the tip, under the name of the ranine artery.

Relations.—Its first, or oblique, portion is superficial, being contained in the same triangular space as the superior thyroid artery, resting upon the middle constrictor of the pharynx, and covered by the Platysma and fascia of the neck. Its second, or curved, portion also lies upon the middle constrictor, being covered at first by the tendon of the Digastric and the Stylo-hyoid muscle, and afterward by the Hyo-glossus, the latter muscle separating it from the hypoglossal nerve. Its third, or horizontal, portion lies between the Hyo-glossus and Genio-hyo-glossus muscles. The fourth, or terminal, part, under the name of the ranine, runs along the under surface of the tongue to its tip: it is very superficial, being covered only by the mucous membrane, and rests on the Lingualis on the outer side of the Genio-hyo-glossus. The hypoglossal nerve crosses the lingual artery, and then becomes separated from it, in the second part of its course, by the Hyo-glossus muscle.

Branches.—The branches of the lingual artery are—the

Hyoid.

Dorsalis Linguae.

Sublingual.

Ranine.

The Hyoid or Supra-hyoid Branch (ramus hyoideus) runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The Dorsalis Linguae (ramus dorsalis linguae) (Fig. 445) arises from the lingual artery beneath the Hyo-glossus muscle (which, in the figure, has been partly cut away, to show the vessel); it ascends to the dorsum of the tongue, and supplies the mucous membrane, the tonsil, soft palate, and epiglottis, anastomosing with its

¹ Berry. Diseases of the Thyroid Gland
fellow from the opposite side. This artery is frequently represented by two or three small branches.

The Sublingual (a. sublingualis), which may be described as a branch of bifurcation of the lingual artery, arises at the anterior margin of the Hyo-glossus muscle, and runs forward between the Genio-hyo-glossus and the sublingual gland. It supplies the substance of the gland, giving branches to the Mylo-hyoid and neighboring muscles, the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the lower jaw in the substance of the gum to anastomose with a similar artery from the other side.

The Ranine or Deep Lingual (a. profunda linguæ) may be regarded as the other branch of bifurcation. It is usually described as the continuation of the lingual artery; it runs along the under surface of the tongue, resting on the Inferior lingualis, and covered by the mucous membrane of the mouth; it lies on the outer side of the Genio-hyo-glossus, accompanied by the lingual nerve. On arriving at the tip of the tongue it is said to anastomose with the artery of the opposite side, but this is denied by Hyrtl. These vessels in the mouth are placed one on each side of the frenum.

Surgical Anatomy.—The lingual artery may be divided near its origin in cases of cut throat, a complication that not unfrequently happens in this class of wounds; or severe hemorrhage which cannot be restrained by ordinary means may ensue from a wound or deep ulcer of the tongue. In the former case the primary wound may be enlarged if necessary, and the bleeding vessels secured. In the latter case it has been suggested that the lingual artery should be tied near its origin. Ligature of the lingual artery is also occasionally practised, as a palliative measure, in cases of cancer of the tongue, in order to check the progress of the disease by starving the growth, and it is sometimes tied as a preliminary measure to removal of the tongue. The operation is a somewhat difficult one, on account of the depth of the artery, the number of important structures by which it is surrounded, the loose and yielding nature of the parts upon which it is supported, and its occasional irregularity of origin. An incision is to be made in a curved direction from a point one finger's breadth external to the symphysis of the jaw downward to the cornu of the hyoid bone, and then upward to near the angle of the jaw. Care must be taken not to carry this incision too far backward, for fear of endangering the facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. The deep fascia is then to be incised and the submaxillary gland exposed and pulled upward by retractors. A triangular space is now exposed, Lesser's triangle, bounded internally by the posterior border of the Mylo-hyoid muscle: below and externally, by the tendon of the Digastric; and above, by the hypoglossal nerve. The floor of the space is formed by the Hyo-glossus muscle, beneath which the artery lies. The fibres of this muscle are now to be cut through horizontally and the vessel exposed, care being taken, while near the vessel, not to open the pharynx.

Troublesome hemorrhage may occur in the division of the frenum in children if the ranine arteries, which lie on each side of it, are wounded. The student should remember that the operation is always to be performed with a pair of blunt-pointed scissors, and the mucous membrane only is to be divided by a very superficial cut, which cannot endanger any vessel. The scissors, also, should be directed away from the tongue. Any further liberation of the tongue which may be necessary can be effected by tearing.

The Facial or External Maxillary Artery (a. maxillaris externa) (Figs. 392, 393, 394, and 395) arises a little above the lingual, and passes obliquely upward, beneath the Digastric and Stylo-hyoid muscles, and frequently beneath the hypoglossal nerve; it now runs forward under cover of the body of the lower jaw, lodged in a groove on the posterior surface of the submaxillary gland; this may be called the cervical part of the artery. It then curves upward over the body of the jaw at the anterior inferior angle of the Masseter muscle; passes forward and upward across the cheek to the angle of the mouth, then upward along the side of the nose, and terminates at the inner canthus of the eye, under the name of the angular artery (a. angularis). The facial artery, both in the neck and on the face, is remarkably tortuous: in the former situation its tortuosity enables it to accommodate itself to the movements of the pharynx in deglutition, and in the latter to the movements of the jaw and the lips and cheeks.
THE EXTERNAL CAROTID ARTERY

Relations.—In the neck its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastric and Stylo-hyoid muscles and part of the submaxillary gland. It lies upon the middle constrictor of the pharynx, and is separated from the Stylo-glossus and Hyo-glossus muscles by a portion of the submaxillary gland. On the face, where it passes over the body of the lower jaw, it is comparatively superficial, lying immediately beneath the Platysma. In this situation its pulsation may be distinctly felt, and compression of the vessel against the bone can be effectually made. In its course over the face it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomatic muscles. It rests on the Buccinator, the Levator anguli oris, and the Levator labii superioris (sometimes piercing or else passing under this last muscle). The facial vein lies to the outer side of the artery, and takes a more direct course across the face, where it is separated from the artery by a considerable interval. In the neck it lies superficial to the artery. The branches of the facial nerve cross the artery, and branches of the infraorbital nerve lie beneath it.

Branches.—The branches of this vessel may be divided into two sets: those given off below the jaw (cervical), and those on the face (facial).

Fig. 394.—The arteries of the face and scalp.1

1 The muscular tissue of the lips must be supposed to have been cut away, in order to show the course of the coronary arteries.
The Inferior or Ascending Palatine (a. palatine ascendens) passes up between the Stylo-glossus and Stylo-pharyngeus to the outer side of the pharynx, along which it is continued between the Superior constrictor and the Internal pterygoid to near the base of the skull. It supplies the neighboring muscles, the tonsil, and Eustachian tube, and divides, near the Levator palati, into two branches: one follows the course of the Levator palati, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the posterior palatine branch of the internal maxillary artery; the other pierces the Superior constrictor and supplies the tonsil, anastomosing with the tonsillar and ascending pharyngeal arteries.

The Tonsillar (ramus tonsillaris) passes up between the Internal pterygoid and Stylo-glossus, and then ascends along the side of the pharynx, perforating the Superior constrictor, to ramify in the substance of the tonsil and root of the tongue.

The Submaxillary or Glandular Branches (rami glandulares) consist of three or four large vessels, which supply the submaxillary gland, some being prolonged to the neighboring muscles, lymphatic glands, and integument.

The Submental (a. submentalis) (Fig. 392), the largest of the cervical branches, is given off from the facial artery just as that vessel quits the submaxillary gland: it runs forward upon the Mylo-hyoid muscle, just below the body of the jaw and beneath the Digastric; after supplying the surrounding muscles, and anastomosing with the sublingual artery by branches which perforate the Mylo-hyoid muscle, it arrives at the symphysis of the chin, where it turns over the border of the jaw and divides into a superficial and a deep branch; the former passes between the integument and Depressor labii inferioris, supplies both, and anastomoses with the inferior labial. The deep branch passes between the latter muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The Muscular Branches are distributed to the Internal pterygoid and Stylohyoid in the neck, and to the Masseter and Buccinator on the face.
The **Inferior Labial** (a. labialis inferior) (Fig. 394) passes beneath the Depressor anguli oris, to supply the muscles and integument of the chin and lower lip, anastomosing with the inferior coronary and submental branches of the facial, and with the mental branch of the inferior dental artery.

The **Inferior Coronary** (Figs. 394 and 395) is derived from the facial artery, near the angle of the mouth; it passes upward and inward beneath the depressor anguli oris, and, penetrating the Orbicularis oris muscle, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane, inosculating with the artery of the opposite side. This artery supplies the labial glands, the mucous membrane, and muscles of the lower lip, and anastomoses with the inferior labial from the facial and the mental branch of the inferior dental artery.

The **Superior Coronary** (a. labialis superior) (Figs. 394 and 395) is larger and more tortuous in its course than the preceding. It follows the same course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the textures of the upper lip, and gives off in its course two or three vessels which ascend to the nose. One, named the **inferior artery of the septum**, ramifies on the septum of the nostrils as far as the point of the nose, and there anastomoses with the naso-palatine artery; another, the **artery of the ala**, supplies the ala of the nose.

The **Lateralis Nasi** is derived from the facial, as that vessel is ascending along the side of the nose; it supplies the ala and dorsum of the nose, anastomosing with its fellow, the nasal branch of the ophthalmic, the inferior artery of the septum, the artery of the ala, and the infraorbital.

The **Angular Artery** (a. angularis) is the termination of the trunk of the facial; it ascends to the inner angle of the orbit, embedded in the fibres of the Levator labii superioris alaeque nasi, and accompanied by a large vein, the **angular vein**; it distributes some branches on the cheek which anastomose with the infraorbital. After supplying the lacrimal sac and Orbicularis palpebrarum muscle, the angular artery terminates by anastomosing with the nasal branch of the ophthalmic artery.

The anastomoses of the facial artery are very numerous, not only with the vessel of the opposite side, but, in the neck, with the sublingual branch of the lingual; with the ascending pharyngeal; and with the posterior palatine, a branch of the internal maxillary, by its inferior or ascending palatine and tonsillar branches; on the face, with the mental branch of the inferior dental as it emerges from the mental foramen, with the transverse facial, a branch of the temporal; with the infraorbital, a branch of the internal maxillary, and with the nasal branch of the ophthalmic.

**Peculiarities.**—The facial artery not unfrequently arises by a common trunk with the lingual. This vessel is also subject to some variations in its size and in the extent to which it supplies the face. It occasionally terminates as the submental, and not unfrequently supplies the face only as high as the angle of the mouth or nose. The deficiency is then supplied by enlargement of one of the neighboring arteries.

**Surgical Anatomy.**—The passage of the facial artery over the body of the jaw would appear to afford a favorable position for the application of pressure in case of hemorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow and with numerous branches from different sources. In a wound involving the lip it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure-forceps. In order to prevent hemorrhage in cases of removal of diseased growths from the part, the lip should be compressed on each side between the fingers and thumb or by a pair of specially devised clamp-forceps, whilst the surgeon excises the diseased part. In order to stop hemorrhage where the lip has been divided in an operation, it is necessary, in uniting the edges of the wound, to pass the sutures through the cut edges from the skin almost as deep as the mucous surface; by these means not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hemorrhage is prevented by including in the suture...
the divided artery. If the suture is, on the contrary, passed through merely the cutaneous portion of the wound, hemorrhage occurs into the cavity of the mouth. The student should, lastly, observe the relation of the angular artery to the lachrymal sac, and it will be seen that, as the vessel passes up along the inner margin of the orbit, it ascends on its nasal side. In operating for "flatula lacrimalis" the sac should always be opened on its outer side, in order that this vessel may be avoided.

The Occipital Artery (a. occipitalis) (Figs. 392, 393, 394, and 396) arises from the posterior part of the external carotid, opposite the facial, near the lower margin of the Digastric muscle. At its origin it is covered by the posterior belly of the Digastric muscle and the Stylo-hyoid muscle, and the hypoglossal nerve winds around it from behind forward; higher up, it passes across the internal carotid artery, the internal jugular vein, and the pneumogastric and spinal accessory nerves;
THE EXTERNAL CAROTID ARTERY

it then ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backward, grooving the surface of the latter bone, being covered by the Sterno-mastoid, Spleniens, Trachelo-mastoid, and Digastric muscles, and resting upon the Rectus lateralis, the Superior oblique, and Complexus muscles; it then changes its course and passes vertically upward, pierces the fascia which connects the cranial attachment of the Trapezius with the Sterno-mastoid, and ascends in a tortuous course over the occiput, as high as the vertex, where it divides into numerous branches (rami occipitales). It is accompanied in the latter part of its course by the great occipital nerve, and occasionally by a cutaneous filament from the suboccipital nerve.

Branches.—The branches given off from this vessel are—

Muscular. Meningeal.
Sterno-mastoid. Mastoid.
Auricular. Arteria Princeps Cervicis.

The Muscular Branches (rami musculares) supply the Digastric, Stylo-hyoid, Spleniens, and Trachelo-mastoid muscles.

The Sterno-mastoid (a. sternocleidomastoidea) is a large and constant branch, generally arising from the artery close to its commencement, but sometimes springing directly from the external carotid. It first passes downward and backward over the hypoglossal nerve, and enters the substance of the muscle in company with the spinal accessory nerve.

The Auricular Branch (ramus auricularis) supplies the back part of the concha. It frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura mater, the diploë, and the mastoid cells.

The Meningeal Branch (ramus meningeus) ascends with the internal jugular vein, and enters the skull through the foramen lacerum posterius, or through the anterior condyloid foramen, to supply the dura mater in the posterior fossa.

The Mastoid Branch (ramus mastoidæus) is a small vessel, by no means constant. It passes into the skull through the mastoid foramen and is distributed upon the dura mater of the posterior fossa.

The Arteria Princeps Cervicis (ramus descendens), the largest branch of the occipital, descends along the back part of the neck and divides into a superficial and a deep portion. The former runs beneath the Spleniens, giving off branches which perforate that muscle to supply the Trapezius, which anastomose with the superficial cervical artery, a branch of the Transversalis colli: the latter passes beneath the Complexus between it and the Semispinalis colli, and anastomoses with branches from the vertebral and with the deep cervical artery, a branch of either the superior intercostal or the subclavian. The anastomosis between these vessels serves mainly to establish the collateral circulation after ligation of the carotid or subclavian artery.

The cranial branches (rami occipitales) of the occipital artery are distributed upon the occiput; they are very tortuous, and lie between the integument and Occipito-frontalis, anastomosing with the artery of the opposite side, the posterior auricular and temporal arteries. They supply the back part of the Occipito-frontalis muscle, the integument, and pericranium.

The Posterior Auricular Artery (a. auricularis posterior) (Figs. 392, 393, and 394) is a small vessel which arises from the external carotid, above the Digastric and Stylo-hyoid muscles, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into its two terminal branches, the auricular and mastoid. Just before arriving at the mastoid process, this artery is crossed by the facial nerve, and has beneath it the spinal accessory nerve.
Branches.—Besides several small branches to the Digastric, Stylo-hyoid, and Sterno-mastoid muscles and to the parotid gland, this vessel gives off three branches: 

Stylo-mastoid.  
Auricular.  
Mastoid.

The Stylo-mastoid Branch (a. stylomastoidea) enters the stylo-mastoid foramen, and supplies the tympanum, mastoid cells, and semicircular canals. In the young subject a branch from this vessel forms, with the tympanic branch from the internal maxillary, a vascular circle, which surrounds the membrana tympani, and from which delicate vessels ramify on that membrane. It anastomoses with the petrosal branch of the middle meningeal artery by a twig, which enters the hiatus Fallopii.

The Auricular Branch (ramus auricularis), one of the terminal branches, ascends behind the ear, beneath the Retrahens auriculam muscle, and is distributed to the back part of the cartilage of the ear, upon which it ramifies minutely, some branches curving round the margin of the fibro-cartilage, others perforating it, to supply its anterior surface. It anastomoses with the posterior branch of the superficial temporal and also with the anterior auricular branches.

The Mastoid Branch (ramus mastoideus) passes backward, over the Sterno-mastoid muscle, to the scalp above and behind the ear. It supplies the posterior belly of the Occipito-frontalis muscles and the scalp in this situation. It anastomoses with the occipital artery.

The Ascending Pharyngeal Artery (a. pharyngea ascendens) (Figs. 392 and 393), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and the Stylopharyngeus muscle. It arises from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Rectus capitis anticus major muscle.

Branches.—Its branches may be subdivided into four sets:

Prevertebral.  
Pharyngeal.  
Tympanic.  
Meningeal.

The Prevertebral Branches are numerous small vessels which supply the Recti capitis antici and Longus colli muscles, the sympathetic, hypoglossal, and pneumogastric nerves, and the lymphatic glands. They anastomose with the ascending cervical artery.

The Pharyngeal Branches (rami pharyngei) are three or four in number. Two of these descend to supply the middle and inferior Constrictors and the Stylo-pharyngeus, ramifying in the substance of the muscles and in the submucous tissue of the mucous membrane lining them. The largest of the pharyngeal branches passes inward, running upon the Superior constrictor, and sends ramifications to the soft palate and tonsil, which take the place of the ascending palatine branch of the facial artery when that vessel is of small size. A twig from this branch supplies the Eustachian tube.

The Tympanic Branch (a. tympanica inferior) is a small artery which passes through a minute foramen in the petrous portion of the temporal bone, in company with the tympanic branch of the Glosso-pharyngeal nerve to supply the inner wall of the tympanum and anastomose with the other tympanic arteries.

The Meningeal Branches consist of several small vessels, which pass through foramina in the base of the skull, to supply the dura mater. One, the posterior meningeal (a. meningea posterior), enters the cranium through the foramen lacerum posterius; a second passes through the foramen lacerum medium; and occasionally a third through the anterior condyloid foramen. They are all distributed to the dura mater.
Surgical Anatomy.—The ascending pharyngeal artery has been wounded from the throat, as in the case in which the stem of a tobacco-pipe was driven into the vessel, causing fatal hemorrhage. After removal of the tonsil there is sometimes severe bleeding. This is almost never due to wounding of the internal carotid artery, as the latter vessel, if normally placed, is too far away to be damaged. The bleeding comes from branches of the ascending pharyngeal, tonsillar, or ascending palatine arteries.

The Superficial Temporal Artery (a. temporalis superficialis) (Fig. 392, 393, and 394), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It commences in the substance of the parotid gland, in the interspace between the neck of the lower jaw and the external auditory meatus, crosses over the posterior root of the zygoma, passes beneath the Attrahens auriculam muscle, lying on the temporal fascia, and divides, about two inches above the zygomatic arch, into two branches, an anterior and a posterior. This vessel is accompanied by the auriculo-temporal nerve.

The Anterior Temporal runs tortuously upward and forward to the forehead, supplying the muscles, integument, and pericranium in this region, and anastomoses with the supra-orbital and frontal arteries. The terminal portion of the anterior branch is called the frontal artery (ramus frontalis).

The Posterior Temporal, larger than the anterior, curves upward and backward along the side of the head, lying superficial to the temporal fascia, and inosculates with its fellow of the opposite side, and with the posterior auricular and occipital arteries. The terminal portion of the posterior branch is named the parietal artery (ramus parietalis).

The superficial temporal artery, as it crosses the zygoma, is covered by the Attrahens auriculam muscle, and by a dense fascia given off from the parotid gland; it is crossed by the temporo-facial division of the facial nerve and one or two veins, and is accompanied by the auriculo-temporal nerve, which lies behind it. Besides some twigs to the parotid gland, the articulation of the jaw, and the Masseter muscles.

Branches.—The branches of the superficial temporal artery are the—

Transverse Facial.  
Middle Temporal.  
Orbital.  
Anterior Auricular.

The Transverse Facial Branch (a. transversa faciei) is given off from the temporal before that vessel quits the parotid gland; running forward through its substance, it passes transversely across the face, between Stenson's duct and the lower border of the zygoma, and divides on the side of the face into numerous branches, which supply the parotid gland, the Masseter muscle, and the integument, anastomosing with the facial, masseteric, and infra-orbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve. It is sometimes a branch of the external carotid.

The Middle Temporal Artery (a. temporalis media) arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the Temporal muscle, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off an orbital branch, which runs along the upper border of the zygoma, between the two layers of the temporal fascia, to the outer angle of the orbit. This branch, which may arise directly from the superficial temporal artery, supplies the Orbicularis palpebrarum, and anastomoses with the lachrymal and palpebral branches of the ophthalmic artery.

The Orbital Artery (a. zygomaticoorbitalis) comes off from the temporal just above the zygoma and is distributed to the upper orbital margin.

The Anterior Auricular Branches (rami auriculares anteriores) are distributed to the anterior portion of the pinna, the lobule, and part of the external meatus, anastomosing with branches of the posterior auricular.
Surgical Anatomy.—Formerly the operation of arteriotomy was performed upon this vessel in cases of inflammation of the eye or brain, but at the present time the operation is obsolete. If the student will consider the relations of the trunk of the vessels as it crosses the zygomatic arch, with the surrounding structures, he will observe that it is covered by a thick and dense fascia, crossed by one of the main divisions of the facial nerve and one or two veins, and accompanied by the auriculo-temporal nerve. The anterior branch, on the contrary, is subcutaneous, and is a large vessel.

The Internal Maxillary Artery (a. maxillaris interna) (Figs. 397 and 398), the larger of the two terminal branches of the external carotid, arises from that vessel opposite the neck of the condyle of the lower jaw, and is at first imbedded in the

![Diagram of the internal maxillary artery and its branches.](image)

Fig. 397.—The internal maxillary artery and its branches.

![Diagram of the plan of the branches.](image)

Fig. 398.—Plan of the branches.

substance of the parotid gland; it passes inward between the ramus of the jaw and the internal lateral ligament, and then upon the outer surface of the External pterygoid muscle to the spheno-maxillary fossa, to supply the deep structures of the face. For convenience of description it is divided into three portions: a maxillary, a pterygoid, and spheno-maxillary.

In the first part of its course, the maxillary portion, the artery passes horizontally forward and inward, between the ramus of the jaw and the internal lateral ligament. The artery here lies parallel to and a little below the auriculo-temporal nerve; it crosses the inferior dental nerve, and lies along the lower border of the External pterygoid muscle.
**THE EXTERNAL CAROTID ARTERY**

In the second part of its course, the **pterygoid portion**, it runs obliquely forward, and upward upon the outer surface of the External pterygoid muscle, being covered by the ramus of the lower jaw and lower part of the Temporal muscle; or it may pass on the inner surface of the External pterygoid muscle to reach the interval between its two heads, between which it passes to reach the sphenomaxillary fossa.

In the third part of its course, the **sphenomaxillary portion**, it approaches the superior maxillary bone, and enters the sphenomaxillary fossa in the interval between the two heads of the External pterygoid muscle, where it lies in relation with Meckel's ganglion, and gives off its terminal branches.

The branches of this vessel may be divided into three groups, corresponding with its three divisions.

**Branches of the First or Maxillary Portion** (Fig. 308):

- Anterior Tympanic.
- Deep Auricular.
- Middle Meningeal.
- Small Meningeal.
- Inferior Dental.

The **Anterior Tympanic Branch** (*a. tympanica anterior*) passes upward behind the articulation of the lower jaw, enters the tympanum through the Glaserian fissure, and ramifies upon the membrana tympani, forming a vascular circle around the membrane with the stylo-mastoid artery, and anastomosing with the Vidian and the tympanic branch from the internal carotid.

The **Deep Auricular Branch** (*a. auricularis profunda*) often arises in common with the preceding. It passes upward in the substance of the parotid gland, behind the temporo-maxillary articulation, pierces the cartilaginous or bony wall of the external auditory meatus, and supplies its cuticular lining and the outer surface of the membrana tympani.

The **Middle Meningeal Branch** (*a. meningea media*) is the largest of the branches which supply the dura mater. It arises from the internal maxillary, between the internal lateral ligament and the neck of the jaw, and passes vertically upward between the two roots of the auriculo-temporal nerve to the foramen spinosum of the sphenoid bone. On entering the cranium it divides into two branches, anterior and posterior. The **anterior branch**, the larger, crosses the great ala of the sphenoid, and reaches the groove, or canal, in the anterior inferior angle of the parietal bone; it then divides into two branches which spread out between the dura mater and internal surface of the cranium, one passing upward over the parietal bone as far as the vertex, and sending rami backward to the occipital bone, the other passing front to the inner surface of the frontal bone. The **posterior branch** crosses the squamous portion of the temporal, and on the inner surface of the parietal bone divides into branches which supply the posterior part of the dura mater and cranium. The branches of this vessel are distributed partly to the dura mater, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal arteries.

The middle meningeal on entering the cranium gives off the following collateral branches: 1. Numerous small vessels to the Gasserian ganglion, and to the dura mater in this situation. 2. A branch, the **petrosal branch** (*ramus petrosus superficialis*), which enters the hiatus Fallopii, supplies the facial nerve, and anastomoses with the stylo-mastoid branch of the posterior auricular artery. 3. A minute **superior tympanic branch** (*a. tympanica superior*), which runs in the canal for the Tensor tympani muscle, and supplies this muscle and the lining membrane of the canal. 4. **Orbital branches**, which pass through the sphenoidal fissure, or through separate canals in the great wing of the sphenoid to anastomose with the lachrymal or other branches of the ophthalmic artery. 5. **Temporal** or **anastomotic branches**, which pass through foramina in the great wing of the...
sphenoid bone and anastomose in the temporal fossa with the deep temporal arteries.

**Surgical Anatomy.**—The middle meningeal is an artery of considerable surgical importance, as it may be injured in fractures of the temporal region of the skull. The vessel may be ruptured by traumaism, even though the skull escapes fracture. Rupture of the middle meningeal artery will be followed by considerable hemorrhage between the bone and dura mater, which may cause compression of the brain and require the operation of trephining for its relief. This artery crosses the anterior inferior angle of the parietal bone at a point 1\(\frac{1}{4}\) inches behind the external angular process of the frontal bone, and 1\(\frac{1}{2}\) inches above the zygoma. From this point the anterior branch passes upward and slightly backward to the sagittal suture, lying about \(\frac{1}{4}\) inch behind the coronal suture. The posterior branch passes upward and backward over the squamous portion of the temporal bone. In order to expose the artery as it lies in the groove in the parietal bone, a semilunar incision, with its convexity upward, should be made, commencing an inch behind the external angular process, and carried backward for two inches. The structures cut through are: (1) skin; (2) superficial fascia, with branches of the superficial temporal vessels and nerves; (3) the fascia continued down from the aponeurosis of the Occipito-frontalis; (4) the two layers of the temporal fascia; (5) the temporal muscle; (6) the deep temporal vessels; (7) the pericranium. The bone is trephined, the clot removed, and the vessel secured by ligatures, suture ligatures, or gauze packing.

The **Small Meningeal Branch** (ramus meningeus accessorius) is sometimes derived from the preceding, usually from the internal maxillary. It enters the skull through the foramen ovale, and supplies the Gasserian ganglion and dura mater.

The **Mandibular, Inferior Alveolar** or **Inferior Dental Branch** (a. alveolaris inferior) descends with the inferior dental nerve to the foramen on the inner side of the ramus of the jaw. It runs along the dental canal in the substance of the bone, accompanied by the nerve, and opposite the first bicuspid tooth divides into two branches, the incisor and mental; the **incisor branch** is continued forward beneath the incisor teeth as far as the symphysis, where it anastomoses with the artery of the opposite side; the **mental branch** (a. mentalis) escapes with the nerve at the mental foramen, supplies the structures composing the chin, and anastomoses with the submental, inferior labial and inferior coronary arteries. Near its origin the inferior dental artery gives off a **lingual branch**, which descends with the lingual (gustatory) nerve and supplies the mucous membrane of the mouth. As the inferior dental artery enters the foramen it gives off a **mylo-hyoid branch** (ramus mylohyoideus), which runs in the mylo-hyoid groove, and ramifies on the under surface of the Mylo-hyoid muscle. The dental and incisor arteries during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the fangs and supply the pulp of the teeth.

**Branches of the Second or Pterygoid Portion** (Fig. 398):

- Deep Temporal.
- Pterygoid.
- Masseteric.
- Buccal.

These branches are distributed, as their names imply, to the muscles in the maxillary region.

The **Deep Temporal Branches**, two in number, **anterior** (a. temporalis profunda anterior) and **posterior** (a. temporalis profunda posterior), each occupy that part of the temporal fossa indicated by its name. Ascending between the Temporal muscle and pericranium, they supply that muscle and anastomose with the middle temporal artery. The anterior branch communicates with the lachrymal artery through small branches which perforate the malar bone and great wing of the sphenoid.

The **Pterygoid Branches** (rami pterygoidei), irregular in their number and origin, supply the Pterygoid muscles.
The **Masseteric** (*a. masseterica*) is a small branch which passes outward, above the sigmoid notch of the lower jaw, to the deep surface of the Masseter muscle. It supplies that muscle, and anastomoses with the masseteric branches of the facial and with the transverse facial artery.

The **Buccal** (*a. buccinatoria*) is a small branch which runs obliquely forward between the Internal pterygoid and the ramus of the jaw, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial artery.

**Branches of the Third or Spheno-maxillary Portion (Fig. 398):**

- Superior Alveolar or Alveolar.
- Infraorbital.
- Descending or Posterior Palatine.
- Vidian.
- Pterygo-palatine.
- Naso- or Spheno-palatine.

The **Superior Alveolar, Alveolar or Posterior Dental Branch** (*a. alveolaris superior posterior*) is given off from the internal maxillary by a common branch with the infraorbital, and just as the trunk of the vessel is passing into the spheno-maxillary fossa. Descending upon the tuberosity of the superior maxillary bone, it divides into numerous branches, some of which enter the posterior dental canals, to supply the upper molar and bicuspid teeth and the lining of the antrum, and others are continued forward on the alveolar process to supply the gums of the upper jaw.

The **Infraorbital** (*a. infraorbitalis*) appears, from its direction, to be the continuation of the trunk of the internal maxillary. It *arises* from that vessel by a common trunk with the preceding branch, and runs along the infra-orbital canal with the superior maxillary nerve, emerging upon the face at the infra-orbital foramen, beneath the Levator labii superioris muscle. Whilst contained in the canal, it gives off branches which ascend into the orbit, and assist in supplying the Inferior rectus and Inferior oblique muscles and the lacrimal gland. Other branches, **anterior dental** (*aa. alveolares superiores anteriores*), descend through the anterior dental canals in the bone, to supply the mucous membrane of the antrum and the front teeth of the upper jaw. On the face, some branches pass upward to the inner angle of the orbit and the lacrimal sac, anastomosing with the angular branch of the facial artery; other branches pass inward toward the nose, anastomosing with the nasal branch of the ophthalmic; and other branches descend beneath the Levator labii superioris muscle, and anastomose with the transverse facial and buccal arteries.

The four remaining branches arise from that portion of the internal maxillary which is contained in the spheno-maxillary fossa.

The **Descending or Posterior Palatine** (*a. palatina descendens*) descends through the posterior palatine canal with the anterior palatine branch of Meckel’s ganglion, and, emerging from the posterior palatine foramen, runs forward in a groove on the inner side of the alveolar border of the hard palate to the anterior palatine canal, where the terminal branch of the artery passes upward through the foramen of Stenson to anastomose with the naso-palatine artery. Its branches are distributed to the gums, the mucous membrane of the hard palate, and the palatine glands. Whilst it is contained in the palatine canal it gives off branches which descend in the accessory palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine artery.

**Surgical Anatomy.**—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as the vessel is in danger of being wounded, and may give rise to formidable hemorrhage. In case it should be wounded it may be necessary to plug the posterior palatine canal in order to arrest the bleeding. This artery may bleed furiously in the operation of resection of the upper jaw.
The Vidian Branch (a. canalis pterygoidei) passes backward along the Vidian canal with the Vidian nerve. It is distributed to the upper part of the pharynx and Eustachian tube, sending a small branch into the tympanum, which anastomoses with the other tympanic arteries.

The Pterygo-palatine is a very small branch, which passes backward through the pterygo-palatine canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and Eustachian tube.

The Naso- or Spheno-palatine (a. sphenopalatina) passes through the sphenopalatine foramen into the cavity of the nose, at the back part of the superior meatus, and divides into two branches: one internal, the naso-palatina or artery of the septum, passes obliquely downward and forward along the septum nasi, supplies the mucous membrane, and anastomoses in front with the terminal branch of the descending palatine and the inferior artery of the septum, which is a branch of the superior coronary. The external branches, two or three in number, supply the mucous membrane covering the lateral wall of the nose, the antrum, and the ethmoid and sphenoid cells.

SURGICAL ANATOMY OF THE TRIANGLES OF THE NECK
(Fig. 269).

The student having considered the relative anatomy of the large arteries of the neck and their branches, and the relations they bear to the veins and nerves, should now examine these structures collectively, as they present themselves in certain regions of the neck, in each of which important operations are constantly being performed.

The side of the neck presents a somewhat quadrilateral outline, limited, above, by the lower border of the body of the jaw, and an imaginary line extending from the angle of the jaw to the mastoid process; below, by the prominent upper border of the clavicle; in front, by the median line of the neck; behind, by the anterior margin of the Trapezius muscle. This space is subdivided into two large triangles by the Sterno-mastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below to the mastoid process above. The triangular space in front of this muscle is called the anterior triangle; and that behind it, the posterior triangle.

Anterior Triangle of the Neck.—The anterior triangle is bounded in front, by an imaginary line extending from the chin to the sternum; behind, by the anterior margin of the Sterno-mastoid; its base, directed upward, is formed by the lower border of the body of the jaw and an imaginary line extending from the angle of the jaw to the mastoid process; its apex is below, at the sternum. This space is subdivided into three smaller triangles by the Digastric muscle above and the anterior belly of the Omo-hyoid below. These smaller triangles are named, from below upward, the inferior carotid, the superior carotid, and the submaxillary triangle.

The Inferior Carotid Triangle or the Triangle of Necessity is bounded, in front, by the median line of the neck; behind, by the anterior margin of the Sterno-mastoid; above, by the anterior belly of the Omo-hyoid; and is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are some of the descending branches of the superficial cervical plexus. Beneath these superficial structures are the Sterno-hyoid and Sterno-thyroid muscles, which, together with the anterior margin of the Sterno-mastoid, conceal the lower part of the common carotid artery.\(^1\) The floor of this triangle is formed

\(^1\) Therefore the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sterno-mastoid muscle; that is to say, lie behind the anterior border of that muscle, which forms the posterior border of the triangle. But, as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it has seemed expedient to study the relations of all these parts together.—Ed. of 15th English edition.
by the Longus colli muscle below and by the Scalenus anticus muscle above, between which muscles the vertebral artery and vein will be found passing into the foramen of the transverse process of the sixth cervical vertebra. A small portion of the origin of the Rectus capitis anticus major may also be seen on the floor of the space.

The common carotid artery is enclosed within its sheath, together with the internal jugular vein and pneumogastric nerve; the vein lying on the outer side of the artery on the right side of the neck, but overlapping it below on the left side; the nerve lying between the artery and vein, on a plane posterior to both. In front of the sheath are a few filaments descending from the loop of communication between the Descendens and communicans hypoglossi; behind the sheath are seen the inferior thyroid artery, the recurrent laryngeal nerve, and the sympathetic nerve; and on its inner side, the trachea, the thyroid gland—much more prominent in the female than in the male—and the lower part of the larynx. By cutting into the upper part of this space and slightly displacing the Sterno-mastoid muscle the common carotid artery may be tied below the Omo-hyoid muscle.

The Superior Carotid Triangle or the Triangle of Election is bounded, behind, by the Sterno-mastoid; below, by the anterior belly of the Omo-hyoid; and above, by the posterior belly of the Digastric muscle. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and superficial cervical nerves. Its floor is formed by parts of the Thyro-hyoid and Hyo-glossus muscles, and the Inferior and Middle constrictor muscles of the pharynx. This space, when dissected, is seen to contain the upper part of the common carotid artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are occasionally somewhat concealed from view by the anterior margin of the Sterno-mastoid muscle, which overlaps them. The external and internal carotid lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space: the superior thyroid, running forward and downward; the lingual, directly forward; the facial, forward and upward; the occipital, backward; and the ascending pharyngeal directly upward on the inner side of the internal carotid. The veins met with are: the internal jugular, which lies on the outer side of the common and internal carotid arteries, and veins corresponding to the above-mentioned branches of the external carotid—viz., the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital, all of which accompany their corresponding arteries and terminate in the internal jugular. The nerves in this space are the following: In front of the sheath of the common carotid is the descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotids above, curving round the occipital artery at its origin. Within the sheath, between the artery and vein, and behind both, is the pneumogastric nerve; behind the sheath, the sympathetic. On the outer side of the vessels the spinal accessory nerve runs for a short distance before it pierces the Sterno-mastoid muscle; and on the inner side of the external carotid, just below the hyoid bone, may be seen the internal laryngeal nerve; and, still more inferiorly, the external laryngeal nerve. The upper part of the larynx and lower part of the pharynx are also found in the front part of this space.

The Submaxillary Triangle corresponds to the part of the neck immediately beneath the body of the jaw. It is bounded, above, by the lower border of the body of the jaw and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric muscle and the Stylo-hyoid muscle; in front, by the anterior belly of the Digastric. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and ascending filaments of the superficial cervical nerves. Its floor is formed by the Mylo-hyoid and Hyo-glossus muscles. This space contains, in front, the sub-
maxillary gland, superficial to which is the facial vein, while imbedded in it are the facial artery and its glandular branches; beneath this gland, on the surface of the Mylo-hyoid muscle, are the submental artery and the mylo-hyoid artery and nerve. The posterior part of this triangle is separated from the anterior part by the stylo-maxillary ligament: it contains the external carotid artery, ascending deeply in the substance of the parotid gland: this vessel here lies in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, temporal, and internal maxillary branches: more deeply are the internal carotid artery, the internal jugular vein, and the pulmonary nerve, separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles and the glosso-pharyngeal nerve.¹

**Posterior Triangle of the Neck.**—The posterior triangle is bounded, in *front*, by the Sterno-mastoid muscle; *behind*, by the anterior margin of the Trapezius; its *base* corresponds to the middle third of the clavicle; its *apex*, to the occiput. The space is crossed, about an inch above the clavicle, by the posterior belly of the Omo-hyoid, which divides it unequally into two, an *upper* or *occipital* and a *lower* or *subclavian* triangle.

The *Occipital Triangle*, the larger division of the posterior triangle, is bounded, in *front*, by the Sterno-mastoid; *behind*, by the Trapezius; *below*, by the Omo-hyoid. Its floor is formed from above downward by the Splenius, Levator anguli scapulae, and the Middle and posterior scaleni muscles. It is covered by the integument, the Platysma below, the superficial and deep fasciae; the spinal accessory nerve is directed obliquely across the space from the Sterno-mastoid, which it pierces, to the under surface of the Trapezius; below, the descending branches of the cervical plexus and the transversalis colli artery and vein cross the space. A chain of lymphatic glands is also found running along the posterior border of the Sterno-mastoid, from the mastoid process to the root of the neck.

The *Subclavian Triangle*, the smaller of the two posterior triangles, is bounded, *above*, by the posterior belly of the Omo-hyoid; *below*, by the clavicle, its base, directed forward, being formed by the Sterno-mastoid. The size of the subclavian triangle varies according to the extent of attachment of the clavicular portion of the Sterno-mastoid and Trapezius muscles, and also according to the height at which the Omo-hyoid crosses the neck above the clavicle. Its height also varies much according to the position of the arm, being much diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downward, when that bone is depressed. This space is covered by the integument, the Platysma, the superficial and deep fasciae, and crossed by the descending branches of the cervical plexus. Just above the level of the clavicle the third portion of the subclavian artery curves outward and downward from the outer margin of the Scalenum anticus, across the first rib, to the axilla. Sometimes this vessel rises as high as an inch and a half above the clavicle, or to any point intermediate between this and its usual level. Occasionally it passes in front of the Scalenum anticus or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is usually not seen in this space; but it occasionally rises as high as the artery, and has even been seen to pass with that vessel behind the Scalenum anticus. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely behind the clavicle are the supra-scapular vessels, and traversing its upper angle in the same direction, the transversalis colli artery and vein. The external jugular vein runs vertically downward behind the posterior border of the Sterno-mastoid muscle, to terminate in the

¹ The same remark will apply to this triangle as was made about the inferior carotid triangle. The structures enumerated as contained in the back part of the space lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland and its boundaries (on account of the frequency of surgical operations on this gland), all these parts are spoken of together.—Ed. of 15th English edition.
subclavian vein; it receives the transverse cervical and suprascapular veins, which occasionally form a plexus in front of the artery, and a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavius muscle also crosses this triangle about its middle. A lymphatic gland is also found in the space. Its floor is formed by the first rib with the first digitation of the Serratus magnus.

The Internal Carotid Artery (A. Carotis Interna).

The internal carotid artery supplies the anterior part of the brain, the eye, and its appendages, and sends branches to the forehead and nose. Its size in the adult is equal to that of the external carotid, though in the child it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. It occasionally has one or two flexures.
near the base of the skull, whilst in its passage through the carotid canal and along the side of the body of the sphenoid bone it describes a double curve which resembles somewhat the letter S placed horizontally. These curvatures most probably diminish the velocity of the current of blood, by increasing the extent of surface over which it moves and adding to the impediment produced from friction.

In considering the course and relations of this vessel it may be conveniently divided into four portions: the cervical, petrous, cavernous, and cerebral portions. **Cervical Portion.**—This portion of the internal carotid commences at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upward, in front of the transverse processes of the three upper cervical vertebrae, to the carotid canal in the petrous portion of the temporal bone. It is superficial at its commencement, being contained in the superior carotid triangle, and lying on the same level as the external carotid, but behind that artery overlapped by the Sterno-mastoid and covered by the deep fascia, Platysma, and integument: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastric and Stylo-hyoid muscles, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glossopharyngeal nerve, and pharyngeal branch of the pneumogastric.

**Relations.**—It is in relation, **behind**, with the Rectus capitis anticus major, the superior cervical ganglion of the sympathetic, and superior laryngeal nerve; **externally**, with the internal jugular vein and pneumogastric nerve, the nerve lying on a plane posterior to the artery; **internally**, with the pharynx, tonsil, the superior laryngeal nerve, and ascending pharyngeal artery. At the base of the skull the glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

**Plan of the Relations of the Internal Carotid Artery in the Neck.**

**In front.**
- Skin, superficial and deep fasciae.
- Platysma.
- Sterno-mastoid.
- Occipital and posterior auricular arteries.
- Hypoglossal nerve.
- Parotid gland.
- Stylo-glossus and Stylo-pharyngeus muscles.
- Glossopharyngeal nerve.
- Pharyngeal branch of the pneumogastric.

**Externally.**
- Internal jugular vein.
- Pneumogastric nerve.

**Internally.**
- Pharynx.
- Superior laryngeal nerve.
- Ascending pharyngeal artery.
- Tonsil.

**Behind.**
- Rectus capitis anticus major.
- Sympathetic.
- Superior laryngeal nerve.

**Petrus Portion.**—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and inward, and again ascends as it leaves the canal to enter the cavity of the skull between the lingula and petrosal process. In this canal the artery lies at first in front of the cochlea and tympanum; from the latter cavity it is separated by a thin, bony lamella, which is cribiform in the young subject, and is often absorbed in old age. Farther forward it is separated from the Gasserian ganglion by a thin plate of bone, which forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. Frequently this bony plate is more
or less deficient, and then the ganglion is separated from the artery by a fibrous membrane. The artery is separated from the bony wall of the carotid canal by a prolongation of dura mater, and is surrounded by a number of small veins and by filaments of the carotid plexus, derived from the ascending branch of the superior cervical ganglion of the sympathetic.

**Cavernous Portion.**—The internal carotid artery in this part of its course is situated between the layers of the dura mater forming the cavernous sinus, but is covered by the lining membrane of the sinus. It at first ascends to the posterior clinoid process, then passes forward by the side of the body of the sphenoid bone, and again curves upward on the inner side of the anterior clinoid process, and perforates the dura mater, forming the roof of the sinus. In this part of its course it is surrounded by filaments of the sympathetic nerve, and has in relation with it externally the sixth nerve.

**Cerebral Portion.**—Having perforated the dura mater, on the inner side of the anterior clinoid process, the internal carotid passes between the second and third cranial nerves to the anterior perforated spot at the inner extremity of the fissure of Sylvius, where it gives off its terminal or cerebral branches. This portion of the artery has the optic nerve on its inner side, and the third nerve externally.

**Peculiarities.**—The length of the internal carotid varies according to the length of the neck, and also according to the point of bifurcation of the common carotid. Its origin sometimes takes place from the arch of the aorta; in such rare instances this vessel has been found to be placed nearer the middle line of the neck than the external carotid, as far upward as the larynx, when the latter vessel crossed the internal carotid. The course of the vessel, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was altogether absent: in one of these the common carotid passed up the neck, and gave off the usual branches of the external carotid, the cranial portion of the internal carotid being replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and the foramen ovale and joined to form a single vessel.

**Surgical Anatomy.**—The cervical part of the internal carotid is very rarely wounded. Mr. Cripps, in an interesting paper in the *Medico-Chirurgical Transactions*, compares the rareness of a wound of the internal carotid with one of the external carotid or its branches. It is, however, sometimes injured by a *stab* or *gunshot wound in the neck*, or even occasionally by a *stab from within the mouth*, as when a person receives a thrust from the end of a parasol or falls down with a tobacco-pipe in his mouth. It used to be believed that the internal carotid was occasionally wounded in the removal of the tonsil. Such an accident cannot happen if the artery is normally placed. The severe and sometimes fatal hemorrhage which has followed this operation in a few instances probably had as its source enlarged branches of the ascending pharyngeal, tonsillar, or ascending palatine arteries. Recently, however, Dr. Gwilym G. Davis, of Philadelphia, demonstrated a specimen in which the internal carotid could have been wounded by incision of the tonsil. The indications for ligature are *wounds*, when the vessel should be exposed by a careful dissection and tied above and below the bleeding point; and *aneurism*, which if non-traumatic may be treated by ligature of the common carotid, but if traumatic in origin by exposing the sac and tying the vessel above and below. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The superficial structures being divided and the Sterno-mastoid defined and drawn outward, the cellular tissue must be carefully separated and the posterior belly of the Digastric muscle and the hypoglossal nerve sought for as guides to the vessel. When the artery is found the external carotid should be drawn inward and the Digastric muscles upward, and the aneurism needle passed from without inward.

**Branches.**—The branches given off from the internal carotid artery are—

*From the Petrous portion* . . . . Typanic (internal or deep).

- Arteriae Receptaculi.
- Anterior Meningeal.
- Ophthalmic.
- Anterior Cerebral.
- Middle Cerebral.
- Posterior Communicating.
- Anterior Choroid.

*From the Cavernous portion* . . . .
The cervical portion of the internal carotid gives off no branches.

The **Tympanic (ramus caroticotympanicus)** is a small branch from the petrous portion, which enters the cavity of the tympanum through a minute foramen in the carotid canal, and anastomoses with the tympanic branch of the internal maxillary, and with the stylo-mastoid artery.

The **Arteriae Receptaculi** are numerous small vessels, derived from the internal carotid in the cavernous sinus; they supply the pituitary body, the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of these branches anastomose with branches of the middle meningeal.

The **Anterior Meningeal (a. meningea anterior)** is a small branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

The **Ophthalmic Artery (a. ophthalmica)** arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbit through the optic foramen, below and on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit, and thence horizontally forward, beneath the lower border of the Superior oblique muscle, to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the **frontal** and **nasal branches**. As the artery crosses the optic nerve it is accompanied by the nasal nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris muscles.

**Branches.** — The branches of this vessel may be divided into an **orbital group**, which are distributed to the orbit and surrounding parts, and an **ocular group**, which supply the muscles and globe of the eye:

Muscular.

The Lachrymal (a. lachrimalis) is one of the largest branches derived from the ophthalmic, arising close to the optic foramen; not infrequently it is given off from the ophthalmic artery before it enters the orbit. It accompanies the lachrymal nerve along the upper border of the External rectus muscle, and is distributed to the lachrymal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva; of those supplying the eyelids, two are of considerable size and are named the external palpebral; they run inward in the upper and lower lids respectively, and anastomose with the internal palpebral arteries, forming an arterial circle in this situation. The lachrymal artery gives off one or two malar branches, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; the other appears on the cheek through the malar foramen, and anastomoses with the transverse facial. A branch, the recurrent, is also sent backward through the sphenoidal fissure to the dura mater, which anastomoses with a branch of the middle meningeal artery.

Peculiarities.—The lachrymal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The Supraorbital Artery (a. supraorbitalis) arises from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to arise above all the muscles of the orbit, it passes forward, with the supraorbital nerve, between the periosteum and Levator palpebræ muscle; and, passing through the supraorbital foramen, divides into a superficial and deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the supraorbital artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebræ muscles, and sends a branch inward, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supraorbital foramen it frequently transmits a branch to the diploë.

The Ethmoidal Branches are two in number—posterior (a. ethmoidalis posterior) and anterior (a. ethmoidalis anterior). The former, which is the smaller, passes through the posterior ethmoidal foramen, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater, and nasal branches which descend into the nose through apertures in the cribiform plate, anastomosing with branches of the sphenopalatine. The anterior ethmoidal artery accompanies the nasal nerve through the anterior ethmoidal foramen, supplies the anterior ethmoidal cells and frontal sinuses, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater and nasal branches, which descend into the nose, through the slit by the side of the crista galli, and, running along the groove on the under surface of the nasal bone, supply the skin of the nose.

The Internal Palpebral Arteries (aa. palpebrales mediales), two in number, superior and inferior, arise from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margin, forming a superior tarsal arch (arcus tarseus superior) and an inferior tarsal arch (arcus tarseus inferior), which lie between the Orbicularis muscle and the tarsal plates;
the superior palpebral inosculating at the outer angle of the orbit with the orbital branch of the temporal artery, and with the upper of the two external palpebral branches from the lachrymal artery—the inferior palpebral inosculating, at the outer angle of the orbit, with the lower of the two external palpebral branches from the lachrymal and with the transverse facial artery, and at the inner side of the lid with a branch from the angular artery. From this last anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.
The Frontal Artery (a. frontalis), one of the terminal branches of the ophtalmic, passes from the orbit at its inner angle, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supra-orbital artery and with the frontal artery of the opposite side.

The Nasal Artery (a. dorsalis nasi), the other terminal branch of the ophtalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lacrymal sac, divides into two branches, one of which crosses the root of the nose, the transverse nasal, and anastomoses with the angular artery; the other, the dorsalis nasi, runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side and with the lateral nasal branch of the facial.

The Ciliary Arteries (a. ciliares) are divisible into three groups, the short, long, and anterior. The short ciliary arteries (aa. ciliaris posteriores breves), from six to twelve in number, arise from the ophtalmic or some of its branches; they surround the optic nerve as they pass forward to the posterior part of the eyeball, pierce the sclerotic coat around the entrance of the nerve, and supply the choroid coat and ciliary processes. The long ciliary arteries (aa. ciliaris posteriores longae), two in number, pierce the posterior part of the sclerotic at some little distance from the optic nerve, and run forward, along each side of the eyeball, between the sclerotic and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle, the circulus major, around the circumference of the iris, from which numerous radiating branches pass forward, in its substance, to its free margin, where they form a second arterial circle, the circulus minor, around its pupillary margin. The anterior ciliary arteries (aa. ciliares anteriores) are
derived from the muscular branches; they pass to the front of the eyeball in company with the tendons of the Recti muscles, form a vascular zone beneath the conjunctiva, and then pierces the sclerotic a short distance from the cornea and terminate in the circular major of the iris.

The Arteria Centralis Retinæ is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the optic nerve, but about half an inch behind the eyeball it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the porus opticus. Its mode of distribution will be described in the account of the anatomy of the eye.

The Muscular Branches (rami musculares), two in number, superior and inferior, frequently spring from a common trunk. The superior, the smaller, often wanting, supplies the Levator palpebræ, Superior rectus, and Superior oblique. The inferior, more constant in its existence, passes forward, between the optic nerve and the Inferior rectus muscle, and is distributed to the External, Internal, and Inferior recti, and Inferior oblique. This vessel gives off most of the anterior ciliary arteries. Additional muscular branches are given off from the lachrymal and supraorbital arteries or from the ophthalmic itself.

![Diagram of the internal surface of the cerebrum](image)

**Fig. 463.—Vascular area of the internal surface of the cerebrum.** I. The part supplied by the anterior internal frontal. II. The part supplied by the middle internal frontal. III. The part supplied by the posterior internal frontal. IV. The part supplied by the posterior temporal. V. The part supplied by the occipital, both terminal branches of the posterior cerebral. (After Duret.)

The Anterior Cerebral (a. cerebri anterior) arises from the internal carotid at the inner extremity of the fissure of Sylvius. It passes forward and inward across the anterior perforated space, above the optic nerve, to the commencement of the great longitudinal fissure. Here it comes into close relationship with the anterior cerebral artery of the opposite side, and the two vessels are connected together by a short anastomosing trunk, about two lines in length, the anterior communicating artery. From this point the two vessels run side by side in the longitudinal fissure, curve round the genu of the corpus callosum, and, turning backward, continue along its upper surface to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries.

**Branches.**—In their course the anterior cerebral arteries give off the following branches:

- Antero-median ganglionic.
- Anterior internal frontal.
- Inferior internal frontal.
- Middle internal frontal.
- Posterior internal frontal.
The Antero-median Ganglionic is a group of small arteries which arise at the commencement of the anterior cerebral artery; they pierce the anterior perforated space and lamina cinerea, and supply the head of the caudate nucleus.

The Inferior Internal Frontal Branches or the Internal Orbital Arteries, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and internal orbital convolution.

The Anterior Internal Frontal supplies a part of the marginal convolution, and sends branches over the edge of the hemisphere to the superior and middle frontal convolutions and upper part of the ascending frontal convolution.

The Middle Internal Frontal supplies the corpus callosum, the convolution of the corpus callosum, the inner surface of the first frontal convolution, and the upper part of the ascending frontal convolution.

The Posterior Internal Frontal supplies the lobus quadratus and adjacent outer surface of the hemisphere.

The Anterior Communicating Artery (a. communicans anterior) is a short branch, about two lines in length, but of moderate diameter, connecting together the two anterior cerebral arteries across the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterward divides. Or the vessel may be wholly or partially divided into two; frequently it is longer and smaller than usual. It gives off some of the antero-median ganglionic group of vessels, which are, however, principally derived from the anterior cerebral.

The Middle Cerebral Artery (a. cerebri media) (Fig. 405), the largest branch of the internal carotid, passes obliquely outward along the fissure of Sylvius, and opposite the island of Reil divides into its terminal branches.
Branches.—The branches of the middle cerebral artery are—

Antero-lateral ganglionic. Ascending frontal.  
Inferior external frontal. Ascending parietal.  
Parieto-temporal.

The Antero-lateral Ganglionic Branches are a group of small arteries which arise at the commencement of the middle cerebral artery; they pierce the anterior perforated space and supply the greater part of the caudate nucleus, the lenticular nucleus, the internal capsule, and a part of the optic thalamus. One artery of this group (one of the lenticulo-striate arteries) is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the artery of cerebral hemorrhage. It passes up between the lenticular nucleus and the external capsule, and ultimately ends in the caudate nucleus.

Fig. 405.—The distribution of the middle cerebral artery. (After Charcot.)

The Inferior External Frontal supplies the third or inferior frontal convolution, Broca's convolution, and the outer part of the orbital surface of the frontal lobe.

The Ascending Frontal supplies the ascending frontal convolution.

The Ascending Parietal supplies the ascending parietal convolution and the lower part of the superior parietal convolution.

The Parieto-temporal or Parieto-sphenoidal supplies the supramarginal, the superior, and part of the middle temporal convolutions, and the angular gyrus. It sends branches to the temporal lobe.

The Posterior Communicating Artery (a. communicans posterior) arises from the back part of the internal carotid, runs directly backward, and anastomoses with the posterior cerebral, a branch of the basilar. This artery varies considerably in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other side. From the posterior half of this vessel are given off a number of small branches, the postero-median ganglionic branches, which, with similar vessels from the posterior cerebral, pierce the posterior perforated space and supply the internal surfaces of the optic thalamus and the walls of the third ventricle.

The Anterior Choroid (a. choroidea) is a small but constant branch which arises from the back part of the internal carotid, near the posterior communicating artery. Passing backward and outward between the temporal lobe and the crus
cerebri, it enters the descending horn of the lateral ventricle through the transverse fissure and ends in the choroid plexus. It is distributed to the hippocampus major, corpus fimbriatum, velum interpositum, and choroid plexus.

THE BLOOD-VESSELS OF THE BRAIN.

Recent investigations have tended to show that the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the anatomical lesions of which this part of the nervous system may be the seat; it therefore becomes important to consider a little more in detail the way in which the cerebral vessels are distributed.

The cerebral arteries are derived from the internal carotid and the vertebral, which at the base of the brain form a remarkable anastomosis known as the circle of Willis (circulus arteriosus [Willisi]). The tortuosity of the constituent vessels of the anastomosis lessens the impact of the circulation and saves the brain from damage. The outline of the vessels forming the so-called circle is said by Sappey to be hexagonal, and by Testut to be heptagonal. The circle of Willis is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind by the two posterior cerebrials, branches of the basilar which are connected on each side to the internal carotid by the posterior communicating (Fig. 401). The parts of the brain included within this arterial círcle are the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space. This arrangement of the vessels of the circle of Willis is not invariable; according to Windle it is maintained in little more than half the recorded cases. In the other cases there are various anomalies.
From the circle of Willis arise the three trunks which together supply each cerebral hemisphere. From its anterior part proceed the two anterior cerebri, from its antero-lateral part the middle cerebri, and from its posterior part the posterior cerebri. Each of these principal arteries gives origin to two very different systems of secondary vessels. One of these systems has been named the **central ganglionic system**, and the vessels belonging to it supply the central ganglia of the brain; the other has been named the **cortical arterial system**, and its vessels ramify in the pia mater and supply the cortex and subjacent medullary matter. These two systems, though they have a common origin, do not communicate at any point of their peripheral distribution, and are entirely independent of each other. Though some of the arteries of the cortical system approach, at their terminations, the regions supplied by the central ganglionic system, no communication between the two sets of vessels takes place, and there is between the parts supplied by the two systems a borderland of diminished nutritive activity, where, it is said, softening is especially liable to occur in the brains of old people.

**The Central Ganglionic System.**—All the vessels belonging to this system are given off from the circle of Willis or from the vessels immediately after their origin from it, so that if a circle is drawn at a distance of about an inch from the circle of Willis, it will include the origin of all the arteries belonging to this system (Fig. 406). The vessels of this system form six principal groups: (I.) the **antero-median group**, derived from the anterior cerebri and anterior communicating; (II.) the **postero-median group**, from the posterior cerebri and posterior communicating; (III.) the right and left **antero-lateral group**, from the middle cerebri; and (IV.) the right and left **postero-lateral group**, from the posterior cerebri, after they have wound round the crura cerebri. The vessels belonging to this system are larger than those of the cortical system, and are what Cohnheim has termed **terminal arteries**; that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branches, so that by one of the small

---

Capillary network in the white matter. (After Charcot.)
vessels only a limited area of the central ganglia can be injected; and the injection cannot be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

**The Cortical Arterial System.**—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries, described above. These vessels divide and ramify in the substance of the pia mater, and give off nutrient arteries which penetrate the cortex perpendicularly. These nutrient vessels are divisible into two classes—the long and short. The long—or, as they are sometimes called, the medullary—arteries pass through the gray matter to penetrate the centrum ovale to the depth of about an inch and a half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The short vessels are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the gray matter, the outer and inner zones being sparingly supplied with blood (Fig. 407). The vessels of the cortical arterial system are not so strictly terminal as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though it may be possible, is frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches or its divisions may have the effect of producing softening in a very limited area of the cortex.¹

**ARTERIES OF THE UPPER EXTREMITY.**

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow, but different portions of it have received different names according to the region through which it passes. That part of the vessel which extends from its origin to the outer border of the first rib is termed the subclavian artery; beyond this point to the lower border of the axilla it is termed the axillary artery; and from the lower margin of the axillary space to the bend of the elbow it is termed the brachial artery; here the single trunk terminates by dividing into two branches, the radial and ulnar—an arrangement precisely similar to what occurs in the lower limb.

**THE SUBCLAVIAN ARTERY (A. SUBCLAVIA) (Fig. 408).**

The subclavian artery on the right side arises from the innominate artery opposite the right sterno-clavicular articulation; on the left side it arises from the arch of the aorta. It follows, therefore, that these two vessels must, in the first part of their course, differ in their length, their direction, and their relation with neighboring parts.

In order to facilitate the description of these vessels, more especially from a surgical point of view, each subclavian artery has been divided into three parts. The first portion, on the right side, passes upward and outward from the origin of the vessel to the inner border of the Scalenus anticus. On the left side it ascends nearly vertically, to gain the inner border of that muscle. The second part passes outward, behind the Scalenus anticus; and the third part passes from the outer margin of that muscle, beneath the clavicle, to the outer border of the first rib, where it becomes the axillary artery. The first portion of these two vessels differs so much in its course and in its relations with neighboring parts that it will be described separately. The second and third parts are alike on the two sides.

¹ The student who desires further information on this subject is referred to Charcot's Localization of Cerebral and Spinal Diseases, p. 42 et seq., whence the facts above given have been principally derived.—Ed. of 15th English edition.
First Part of the Right Subclavian Artery (Figs. 389, 390, 392, 408).

On the right side the subclavian artery arises from the arteria innominata, opposite the upper part of the right sterno-clavicular articulation, and passes upward and outward to the inner margin of the Scalenus anticus muscle (Figs. 389, 390, and 408). In this part of its course it ascends a little above the clavicle, the extent to which it does so varying in different cases.

Relations.—It is covered, in front, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sterno-mastoid, the Sterno-hyoid, and Sterno-thyroid muscles, and a second layer of deep fascia. It is crossed by the internal jugular and vertebral veins, and by the pneumogastric nerve and the cardiac branches of the sympathetic nerve. A loop of the sympathetic nerve itself also crosses the artery, forming a ring around the vessels. The anterior jugular vein passes outward in front of the artery but is not in contact with it, being separated from it by the Sterno-hyoid and Sterno-thyroid muscles. Below and behind the artery is the pleura, which separates it from the apex of the lung; behind is the cord of the sympathetic nerve; the recurrent laryngeal nerve winds round the lower and back part of the vessel.

Pleura and apex of lung.

First Part of the Left Subclavian Artery (Figs. 388, 389).
The left subclavian artery arises from the end of the arch of the aorta, opposite the fourth dorsal vertebra, and ascends nearly vertically to the inner margin of the Scalenus anticus muscle. This part of the vessel is, therefore, longer than the right, is situated deeply in the cavity of the chest, and is directed nearly vertically upward, instead of arching outward like the vessel of the opposite side.

Relations.—It is in relation, in front, with the pneumogastric, cardiac, and phrenic nerves, which lie parallel with it, the left carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein and is covered by the Sterno-thyroid, Sterno-hyoid, and Sterno-mastoid muscles; behind, it is in relation with the esophagus, thoracic duct, inferior cervical ganglion of the sympathetic, and Longus colli muscle; higher up, however, the esophagus and thoracic duct lie to its right side; the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. To its inner side are the esophagus, trachea, and thoracic duct; to its outer side, the left pleura and lung.

Second and Third Parts of the Subclavian Artery (Figs. 392, 408).
The Second Portion of the Subclavian Artery lies behind the Scalenus anticus muscle; it is very short, and forms the highest part of the arch described by that vessel.
**Relations.**—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep cervical fascia, the Sterno-mastoid and the Scalenus anticus muscles. On the right side the phrenic nerve is separated from the second part of the artery by the Scalenus anticus muscle, while on the left side the nerve crosses the first part of the artery immediately to the inner edge of the muscle. *Behind*, it is in relation with the pleura and the Scalenus medius muscle. *Above*, with the brachial plexus of nerves. *Below*, with the pleura. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anticus muscle.

**Plan of the Relations of Second Portion of Subclavian Artery.**

*In front.*
- Skin and superficial fascia.
- Platysma and deep cervical fascia.
- Sterno-mastoid.
- Phrenic nerve.
- Scalenus anticus.
- Subclavian nerve.

*Above.*
- Brachial plexus.

*Below.*
- Pleura.

*Behind.*
- Pleura and Middle Scaleneus.

The **Third Portion of the Subclavian Artery** passes downward and outward from the outer margin of the Scalenus anticus muscle to the outer border of the first rib, where it becomes the axillary artery. This portion of the vessel is the most superficial, and is contained in the subclavian triangle (see page 618).

**Relations.**—It is covered, *in front*, by the skin, the superficial fascia, the Platysma, the descending clavicular branches of the cervical plexus, and the deep cervical fascia; by the clavicle, the Subclavius muscle, the suprascapular artery and vein, and the transverse cervical vein; the nerve to the Subclavius muscle passes vertically downward in front of the artery. The external jugular vein crosses the artery at its inner side, and receives the suprascapular and transverse cervical veins, which frequently form a plexus in front of it. The subclavian vein is below and in front of the artery, lying close behind the clavicle. *Behind*, it lies on the Middle scaleneus muscle and the lowest cord of the brachial plexus, formed by the union of the last cervical and first dorsal nerves. *Above* it, and to its outer side, is the brachial plexus and Omo-hyoid muscle. *Below*, it rests on the upper surface of the first rib.

**Plan of the Relations of Third Portion of Subclavian Artery.**

*In front.*
- Skin and superficial fascia.
- Platysma and deep cervical fascia.
- Subclavius muscle, suprascapular artery, and vein.
- The external jugular and transverse cervical veins.
- The clavicle.

*Above.*
- Brachial plexus.
- Omo-hyoid.

*Below.*
- First rib.

*Behind.*
- Scalenus medius.
- Lower cord of brachial plexus.
Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The origin of the right subclavian from the innominate takes place, in some cases, above the sterno-clavicular articulation, and occasionally, but less frequently, in the cavity of the thorax, below that point. Or the artery may arise as a separate trunk from the arch of the aorta. In such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority of cases it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, at its upper or back part, and passes obliquely toward the right side, usually behind the trachea, esophagus, and right carotid, sometimes between the esophagus and trachea to the upper border of the first rib, whence it follows its ordinary course. In very rare instances this vessel arises from the thoracic aorta, as low down as the fourth dorsal vertebra. Occasionally it perforates the Scalenus anticus muscle; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus anticus muscle. The artery may ascend as high as an inch and a half above the clavicle or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out by describing a curve, with its convexity upward at the base of the posterior triangle. The inner end of this curve corresponds to the sterno-clavicular joint, the outer end of the centre of the lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle. The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sterno-mastoid muscle corresponds to the outer border of the Scalenus anticus muscle, so that the third portion of the artery, that part most accessible for operation, lies immediately external to the posterior border of the Sterno-mastoid muscle.

Surgical Anatomy.—The relations of the subclavian arteries of the two sides having been examined, the student should direct his attention to a consideration of the best position in which compression of the vessel may be effected, or in what situation a ligature may be best applied in cases of aneurism or wound.

Compression of the subclavian artery is required in cases of operations about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied—viz., where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon, grasping the side of the neck, should press with his thumb in the angle formed by the posterior border of the Sterno-mastoid with the upper border of the clavicle, downward, backward, and inward against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backward, so as to compress the artery against the Scalenus medius muscle and the transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligature of the subclavian artery may be required in cases of wounds or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligature; and the third part of the artery is that which is most favorable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumor in the axilla the artery is placed at a great depth from the surface, which materially increases the difficulty of the operation. Under these circumstances it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases its arch is about half an inch above the clavicle, occasionally it is as high as an inch and a half, and sometimes so low as to be on a level with the upper border of the clavicle. If the clavicle is displaced, these variations will necessarily make the operation more or less difficult according as the vessel is more or less accessible.

The chief points in the operation of tying the third portion of the subclavian artery are as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side and the shoulder depressed as much as possible, the integument should be drawn downward over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sterno-mastoid, to which may be added a short vertical incision meeting the inner end of the preceding. The object in drawing the skin downward is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downward with the skin. The soft parts should now be allowed to glide up, and the cervical fascia should be divided upon a director, and if the interval between the Trapezius and Sterno-mastoid muscles be insufficient for the per-
formance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen toward the inner side of the wound: this and the suprascapular and transverse cervical veins, which terminate in it, should be held aside. If the external jugular vein is at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omo-hyoid muscle held aside if necessary. In the space beneath this muscle careful search must be made for the vessel: a deep layer of fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for, and, the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurism needle may then be passed around the artery from above downward and inward, so as to avoid including any of the branches of the brachial plexus. If the clavicle is so raised by the tumor that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery and the alteration in position of the surrounding parts.

The second part of the subclavian artery, from being that portion which rises highest in the neck, has been considered favorable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anticus muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the Scalenus anticus muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as a ligature of the third portion, until the Scalenus anticus is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of ligature of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery in which the aneurism encroaches upon the outer portion of the Scalenus muscle to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side this operation has been regarded as almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, presents a series of difficulties which it is very difficult to overcome. Nevertheless, Professor Halsted and Schumpert have each tied successfully the first portion of the left subclavian for aneurism. J. K. Rodgers, of New York, also did it successfully. On the right side the operation is practicable, and has been performed. Dr. Nassau, of Philadelphia, successfully ligated the first part of the right subclavian. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the supine position with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the Sterno-mastoid, meeting the former at an angle. The attachment of both heads of the Sterno-mastoid must be divided on a director and turned outward; a few small arteries and veins, and occasionally the anterior jugular vein, must be avoided, or, if necessary, ligatured in two places and divided, and the Sterno-hyoid and Sterno-thyroid muscles are to be divided in the same manner as the preceding muscle. After tearing through the deep fascia with the finger-nail, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside and the artery secured by passing the needle from below upward, by which the pleura is more effectually avoided. The exact position of the vagus, the recurrent laryngeal, the phrenic and sympathetic nerves should be remembered, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course when it arises from the left side of the aortic arch, and passes in such cases behind the oesophagus or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery the collateral circulation is mainly established by three sets of vessels, thus described in a dissection:

1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the subscapular from the axillary.

2. An internal set produced by the connection of the internal mammary on the one hand, with the superior and long thoracic arteries, and the branches from the subscapular on the other.
"3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminated either in the main trunk or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of the newly formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

"The chief agent in the restoration of the axillary artery below the tumor was the subscapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian, from all of which is received so great an influx of blood as to dilate it to three times its natural size."  

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by—1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrales; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis; 6, the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

Branches.—The branches given off from the subclavian artery are:

Vertebral.  
Thyroid axis.  
Internal mammary.  
Superior intercostal.

On the left side all four branches generally arise from the first portion of the vessel; but on the right side, the superior intercostal usually arises from the second portion of the vessel. On both sides of the body the first three branches arise close together at the inner margin of the Scalenus anticus; in the majority of cases a free interval of from half an inch to an inch exists between the commencement of the artery and the origin of the nearest branch; in a smaller number of cases an interval of more than an inch exists, but it never exceeds an inch and three-quarters. In a very few instances the interval has been found to be less than half an inch. The vertebral artery arises from the upper and posterior part of the subclavian artery, the internal mammary from the lower part of the artery; the thyroid axis from in front and the superior intercostal from behind.

The Vertebral Artery (a. vertebralis) (Fig. 399) is generally the first and largest branch of the subclavian; it arises from the upper and back part of the first portion of the vessel, and, passing upward, enters the foramen in the transverse process of the sixth cervical vertebra, and ascends through the foramina in the transverse processes of all the vertebrae above this. Above the upper border of the axis it inclines outward and upward to the foramen in the transverse process of the atlas, through which it passes; it then winds backward behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone (Fig. 16), and, passing beneath the posterior occipito-atlantal ligament (Figs. 199 and 202), pierces the dura mater and arachnoid, and enters the skull through the foramen magnum. It then passes forward and upward, inclining from the lateral aspect to the front of the medulla oblongata. It unites in the middle line with the vessel of the opposite side at the lower border of the pons Varolii to form the basilar artery (Fig. 401).

Relations.—At its origin it is situated behind the internal jugular and vertebral veins, and is crossed by the inferior thyroid artery: it lies between the Longus colli and Scalenus anticus muscles, having the thoracic duct in front of it on the left side. It rests on the transverse process of the seventh cervical vertebra and the sympathetic nerve. Within the foramina formed by the transverse processes of the vertebrae it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the vertebral vein at the lower part of the neck. It is situated in

1 Guy's Hospital Reports, vol. I., 1836: ease of axillary aneurism, in which Mr. Aston Key had tied the subclavian artery on the outer edge of the Scalenus muscle twelve years previously.

2 The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.—Ed. of 15th English edition.
front of the cervical nerves, as they issue from the intervertebral foramina. While
winding round the articular process of the atlas, it is contained in a triangular
space, the suboccipital triangle, formed by the Rectus capitis posticus major, the
Superior oblique and the Inferior oblique muscles; and at this point is covered
by the Complexus muscle (Fig. 283). The suboccipital nerve here lies between
the artery and the bone. Within the skull, as the artery winds round the medulla
oblongata, it is placed between the hypoglossal nerve and the anterior root of the
suboccipital nerve, beneath the first digitation of the ligamentum denticulatum,
and finally ascends between the basilar process of the occipital bone and the
anterior surface of the medulla oblongata.

Branches.—These may be divided into two sets—those given off in the neck
and those within the cranium.

**Cervical Branches.**
- Lateral Spinal.
- Muscular.

**Cranial Branches.**
- Posterior Meningeal.
- Anterior Spinal.
- Posterior Spinal.
- Posterior Inferior Cerebellar.
- Bulbar.

The **Lateral Spinal Branches** (*rami spinales*) enter the spinal canal through the
intervertebral foramina and divide into two branches. Of these, one passes along
the roots of the nerves to supply the spinal cord and its membranes, anastomosing
with the other arteries of the spinal cord; the other divides into an ascending and
a descending branch, which unite with similar branches from the artery above and
below, so that two lateral anastomotic chains are formed on the posterior surface
of the bodies of the vertebrae near the attachment of the pedicles. From these
anastomotic chains branches are given off to supply the periosteum and the bodies
of the vertebrae, and to communicate with similar branches from the opposite side;
from these communicating branches small branches are given off which join
similar branches above and below, so that a central anastomotic chain is formed
on the posterior surface of the bodies of the vertebrae.

**Muscular Branches** are given off to the deep muscles of the neck, where the
vertebral artery curves round the articular process of the atlas. They anastomose
with the occipital and with the ascending and deep cervical arteries.

The **Posterior Meningeal** (*ramus meningpus*) is a small branch given off from
the vertebral opposite the foramen magnum. It ramifies between the bone and
dura mater in the cerebellar fossa, and supplies the falx cerebelli.

The **Anterior Spinal** (*a. spinalis anterior*) is a small branch which *arises* near
the termination of the vertebral, and, descending in front of the medulla oblongata,
unites with its fellow on the opposite side at about the level of the foramen magnum.
One of these vessels is usually larger than the other, but occasionally they are about
equal in size. The single trunk thus formed descends on the front of the spinal
cord, and is reinforced by a succession of small branches which enter the spinal
canal through the intervertebral foramina; these branches are derived from the
vertebral artery and the ascending cervical branch of the inferior thyroid artery
in the neck; from the intercostal in the dorsal region; and from the lumbar,
ilio-lumbar, and lateral sacral arteries in the lower part of the spine. They unite,
by means of ascending and descending branches, to form a single anterior median
artery, which extends as far as the lower part of the spinal cord. This vessel is
placed in the pia mater along the anterior median fissure; it supplies that mem-
brane and the substance of the cord, and sends off branches at its lower part to
be distributed to the cauda equina, and ends on the central fibrous prolongation
of the cord.
The Posterior Spinal (a. spinalis posterior) arises from the vertebral at the side of the medulla oblongata; passing backward to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina, and by which it is continued to the lower part of the cord and to the cauda equina. Branches from these vessels form a free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. At its commencement it gives off an ascending branch, which terminates on the side of the fourth ventricle.

The Posterior Inferior Cerebellar Artery (a. cerebelli inferior posterior) (Fig. 401), the largest branch of the vertebral, winds backward round the upper part of the medulla oblongata, passing between the origin of the pneumogastric and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches—an internal, which is continued backward to the notch between the two hemispheres of the cerebellum; and an external, which supplies the under surface of the cerebellum as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

The Bulbar Arteries comprise several minute vessels which spring from the vertebral and its branches and are distributed to the medulla oblongata.

Surgical Anatomy.—The vertebral artery has been tied in several instances: 1, for wounds or traumatic aneurism; 2, after ligation of the innominate, either immediately to prevent hemorrhage, or later on to arrest bleeding where it has occurred at the seat of ligation; and 3, in epilepsy. In these latter cases the treatment has been recommended by Dr. Alexander, of Liverpool, in the hope that by diminishing the supply of blood to the posterior part of the brain and the spinal cord—a diminution or cessation of the epileptic fits would result. But, on account of the uncertainty as to what cases, if any, derived benefit from the operation, it has now been abandoned as a treatment for epilepsy. The operation of ligation of the vertebral is performed by making an incision along the posterior border of the Semo-mastoid muscle, just above the clavicle. The muscle is pulled to the inner side, and the anterior tubercle of the transverse process of the sixth cervical vertebra is sought for. A deep layer of fascia being now divided, the interval between the Scalenus anticus and the Longus colli muscles just below their attachment to the tubercle is defined, and the artery and vein are found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle is passed from without inward. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the suboccipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal nerve where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

The Basilar Artery (a. basilaris) (Fig. 401), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in the median pontine groove, under cover of the arachnoid. It ends by dividing into the two posterior cerebral arteries.

Branches.—Its branches are, on each side, the following:

- Transverse.
- Internal Auditory.
- Anterior Inferior Cerebellar.
- Superior Cerebellar.
- Posterior Cerebral.

The Transverse or Pontal Branches (rami ad pontem) supply the substance of the pons Varolii.

The Internal Auditory (a. auditiva interna) accompanies the auditory nerve into the internal auditory meatus. It supplies the internal ear.
The Anterior Inferior Cerebellar Artery (a. cerebelli inferior anterior) passes backward across the crus cerebelli, to be distributed to the anterior border of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The Superior Cerebellar Artery (a. cerebelli superior) on each side arises near the termination of the basilar. It passes outward, immediately behind the third nerve, which separates it from the posterior cerebral, winds round the crus cerebri, close to the fourth nerve, and, arriving at the upper surface of the cerebellum, divides into branches which ramify in the pia mater and, reaching the circumference of the cerebellum, anastomose with the branches of the inferior cerebellar arteries. Several branches are given to the pineal gland, the valve of Vieuwens, and the velum interpositum.

The Posterior Cerebral Artery (a. cerebri posterior) (Figs. 401, 403, 404, and 406), on each side, is the terminal branch of the basilar. It is larger than the preceding, from which it is separated near its origin by the third nerve. Passing outward, parallel to the superior cerebellar artery, and receiving the posterior communicating from the internal carotid, it winds round the crus cerebri, and passes to the under surface of the occipital lobes of the cerebrum, and break up into branches for the supply of the temporal and occipital lobes. The branches of the posterior cerebral artery are:

- Postero-median ganglionic.
- Posterior choroid.
- Postero-lateral ganglionic.

Three terminal

- Anterior temporal.
- Posterior temporal.
- Occipital.

The postero-median ganglionic branches (Fig. 406) are a group of small arteries which arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated space, and supply the internal surfaces of the optic thalamus and the walls of the third ventricle. The posterior choroid enters the interior of the brain beneath the splenium of the corpus callosum, and supplies the velum interpositum and the choroid plexus. The postero-lateral ganglionic branches are a group of small arteries which arise from the posterior cerebral artery, after it has turned round the crus cerebri; they supply a considerable portion of the optic thalamus. The terminal branches are distributed as follows: the first, or the anterior temporal branches, to the under surface of the anterior portion of the temporal lobe; the second, or the posterior temporal branches, to the external occipital and the third temporal convolutions; and the third, or the occipital branches, to the inner and outer surfaces of the occipital lobe.

Circle of Willis (circulus arteriosus [Willisi]).—The remarkable anastomosis which exists between the branches of the internal carotid and vertebral arteries at the base of the brain constitutes the circle of Willis. It is formed in front, by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind, by the two posterior cerebrials, branches of the basilar, which are connected on each side with the internal carotid by the posterior communicating arteries (Fig. 401). It is by this anastomosis that the cerebral circulation is equalized, and provision made for effectually carrying it on if one or more of the branches are obliterated. The parts of the brain included within this arterial circle are—the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The Thyroid Axis (truncus thyreocervicalis) (Figs. 392 and 410) is a short thick trunk which arises from the forepart of the first portion of the subclavian artery, close to the inner border of the Scalessus anticus muscle, and divides, almost immediately after its origin, into three branches—the inferior thyroid, suprascapular, and transversalis colli.
The **Inferior Thyroid Artery** (*a. thyreoides inferior*) (Fig. 392) passes upward, in front of the vertebral artery and Longus colli muscle; then turns inward behind the sheath of the common carotid artery and internal jugular vein, and also behind the sympathetic nerve, the middle cervical ganglion resting upon the vessel, and reaching the lower border of the lateral lobe of the thyroid gland it divides into two branches, which supply the posterior and under part of the organ, and anastomose in its substance with the superior thyroid and with the corresponding artery of the opposite side. (See page 602.) The recurrent laryngeal nerve passes upward, generally behind but occasionally in front of the artery. Its **branches** are:

- **Inferior Laryngeal.**
- **Tracheal.**
- **Esophageal.**
- **Ascending Cervical.**

Muscular.

The **inferior laryngeal branch** (*a. laryngea inferior*) ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the laryngeal branch from the superior thyroid artery and with the inferior laryngeal branch from the opposite side. The **tracheal branches** (*rami tracheales*) are distributed upon the trachea, anastomosing below with the bronchial arteries. The **esophageal branches** (*rami oesophagei*) are distributed to the esophagus, and anastomose with the esophageal branches of the aorta. The **ascending cervical** (*a. cervicalis ascendens*) is a small branch which arises from the inferior thyroid just where that vessel is passing behind the common carotid artery, and runs up on the anterior tubercles of the transverse processes of the cervical vertebrae in the interval between the Scalenus anticus and Rectus capitis anticus major muscles. It gives **muscular branches** (*rami musculares*) to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches (*rami spinales*) into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries. The muscular branches supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx. One of the muscular branches passes between the transverse processes of the fourth and fifth cervical vertebrae and reaches the deep muscles of the neck. It is called the **ramus profundus**.

**Surgical Anatomy.**—The inferior thyroid artery has been tied, in conjunction with the superior thyroid, in cases of bronchocele. An incision is made along the anterior border of the Sterno-mastoid down to the clavicle. After the deep fascia has been divided, the Sterno-mastoid and carotid vessels are drawn outward and the **carotid tubercle** (*Chassaingae's tubere*) sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side of the trachea and esophagus on the inner side. In passing the ligature great care must be exercised to avoid including the recurrent laryngeal nerve, which is occasionally found crossing in front of the vessel. Before extirpating a goitrous lobe of the thyroid the superior and inferior thyroid arteries of the diseased side are to be ligated.

The **Suprascapular or Transversalis Humeri Artery** (*a. transversa scapula*) (Figs. 392 and 409), smaller than the transversalis colli, passes obliquely from within outward, across the root of the neck. It at first passes downward and outward across the Scalenus anticus muscle and phrenic nerve, being covered by the Sterno-mastoid; it then crosses the subclavian artery and the cords of the brachial plexus, and runs outward, behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omo-hyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula, which separates it from the suprascapular nerve, and reaches the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it
supplies branches. It then passes downward behind the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsalis scapulæ branch of the subscapular artery and branches of the posterior scapular arteries. Besides distributing branches to the Sterno-mastoid, Subclavius, and neighboring muscles, it gives off a suprasternal branch, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and a supra-acromial branch (ramus acromialis), which, piercing the Trapezius muscle, supplies the skin over the acromion, anastomosing with the acromial thoracic artery. As the artery passes over the transverse ligament of the scapula, a branch descends into the subscapular fossa, ramifies beneath the subscapular muscle, and anastomoses with the posterior and subscapular arteries. The suprascapular artery also sends branches to the acromio-clavicular and shoulder joints, and a nutrient artery to the clavicle.

Fig. 409.—The scapular and circumflex arteries.

The Transverse Cervical or Transversalis Colli Artery (a. transversa colli) (Fig. 392) passes transversely outward, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the superficial cervical and the posterior scapular. In its passage across the neck it crosses in front of the phrenic nerve, Scaleni muscles, and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sterno-mastoid, Omo-hyoid, and Trapezius muscles. The superficial cervical (ramus ascendens) ascends beneath the anterior margin of the Trapezius, distributing branches to it and to the neighboring muscles and glands in the neck, and anastomosing with the superficial branch of the arteria princeps cervicis. The posterior scapular (ramus descendens) (Fig. 409) passes beneath the Levator anguli scapulæ muscle to the superior angle of the scapula, and then descends along the posterior border of that bone as far as the inferior angle. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The superficial cervical frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.
The **Internal Mammary** (a. mammaea interna) (Fig. 410) arises from the under surface of the first portion of the subclavian artery, opposite the thyroid axis. It passes downward and inward behind the costal cartilage of the first rib to the inner surface of the anterior wall of the chest, resting against the costal cartilages about half an inch from the margin of the sternum; and, at the interval
between the sixth and seventh cartilages, divides into two branches, the musculo-
phrenic and superior epigastric.

Relations.—At its origin it is covered by the internal jugular and subclavian
veins, and as it enters the thorax is crossed from without inward by the phrenic
nerve, and then passes forward close to the outer side of the innominate vein. In
the upper part of the thorax it lies behind the costal cartilages and Internal inter-
costal muscles, and is crossed by the terminations of the upper six intercostal
nerves. At first it lies upon the pleura, but at the lower part of the thorax the
Triangularis sterni separates the artery from this membrane. It has two vae
comites; these unite into a single vein, which joins the innominate vein of its own
side.

Branches.—The branches of the internal mammary are—

- Comes Nervi Phrenici (Superior Phrenic). Anterior Intercostal.
- Mediastinal. Perforating.
- Pericardiac. Musculo-phrenic.
- Sternal. Superior Epigastric.

The Comes Nervi Phrenici or Superior Phrenic (a. pericardiaco-phrenica) is a long
slender branch which accompanies the phrenic nerve, between the pleura and
pericardium, to the Diaphragm. It gives branches to the pericardium and is
distributed upon the Diaphragm, anastomosing with the other phrenic branches
from the internal mammary and with phrenic branches of the abdominal aorta.

The Mediastinal Branches (aa. mediastinales anteriores) are small vessels
which are distributed to the areolar tissue and lymphatic glands in the anterior
mediastinum and to the remains of the thymus gland.

The Pericardiac Branches supply the upper part of the anterior surface of the
pericardium, the lower part receiving branches from the musculo-phrenic artery.

The Sternal Branches (rami sternalis) are distributed to the Triangularis sterni
and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs
from the comes nervi phrenici, anastomose with branches from the intercostal and
bronchial arteries, and form a minute plexus beneath the pleura, which has been
named by Turner the subpleural mediastinal plexus.

The Anterior Intercostal Arteries (rami intercostales) supply the five or six upper
intercostal spaces. The branch corresponding to each space soon divides into
two, or the two branches may come off separately from the parent trunk. The
small vessels pass outward in the intercostal spaces, one, the larger, lying near
the lower margin of the rib above, and the other, the smaller, near the upper
margin of the rib below, and anastomose with the intercostal arteries from the
aorta. They are at first situated between the pleura and the Internal intercostal
muscles, and then between the Internal and External intercostal muscles. They
supply the Intercostal muscles, and, by branches which perforate the External
intercostal muscle, reach the Pectoralis muscles and the mammary gland.

The Perforating or Anterior Perforating Arteries (rami perforantes) correspond
to the five or six upper intercostal spaces. They arise from the internal mam-
mary, pass forward through the intercostal spaces, and, curving outward, supply
the Pectoralis major and the integument. Those which correspond to the second,
third, and fourth spaces are distributed to the mammary gland. In females,
during lactation, these branches are of large size.

The Musculo-phrenic Artery (a. musculophrenica) is directed obliquely down-
ward and outward, behind the cartilages of the false ribs, perforating the Dia-
aphragm at the eighth or ninth rib, and terminating, considerably reduced in size,
opposite the last intercostal space. It gives off anterior intercostal arteries to
each of the intercostal spaces across which it passes; these diminish in size as the
spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backward to the Diaphragm and downward to the abdominal muscles.

The Superior Epigastric (a. epigastrica superior) continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some branches perforate the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inward upon the side of the ensiform appendix, anastomoses in front of that cartilage with the superior epigastric artery of the opposite side. It also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Surgical Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the chest-wall. It is most easily reached by a transverse incision in the second intercostal space.

The Superior Intercostal (truncus costocervicalis) (Figs. 399 and 416) arises from the upper and back part of the subclavian artery, behind the Scalenus anticus muscle on the right side and to the inner side of that muscle on the left side. Passing backward, it gives off the deep cervical branch, and then descends behind the pleura in front of the necks of the first two ribs, and inosculates with the first aortic intercostal. As it crosses the neck of the first rib it lies to the inner side of the anterior division of the first dorsal nerve and to the outer side of the first thoracic ganglion of the sympathetic. In the first intercostal space it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the highest aortic intercostal. Each intercostal gives off a branch to the posterior spinal muscles, and a small branch which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The Deep Cervical Branch (a. cervicalis profunda) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery; occasionally it arises as a separate branch from the subclavian artery. Passing backward, above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis coli muscles, as high as the axis vertebra, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital, and with branches which pass outward from the vertebral. It gives off a special branch which enters the spinal canal through the intervertebral foramen between the seventh cervical and first dorsal vertebrae.

SURGICAL ANATOMY OF THE AXILLA.

The axilla is a pyramidal space, situated between the upper and lateral part of the chest and the inner side of the arm.

Boundaries.—Its apex, which is directed upward toward the root of the neck, corresponds to the interval between the first rib, the upper edge of the scapula, and the clavicle, through which the axillary vessels, the brachial plexus of nerves, and the long thoracic nerve pass. This interval is the cervico-axillary passage.
The base, directed downward, is formed by the integument and a thick layer of fascia, the **axillary fascia** (*fascia axillaris*) (Fig. 313), extending between the lower border of the Pectoralis major in front and the lower border of the Latissimus dorsi behind (page 463). The axillary fascia is perforated at several points. The large central opening is called the **foramen of Langer**. The inner margin of the foramen of Langer is dense and constitutes a part of the **axillary arch**, which is a fibro-muscular slip derived from the latissimus dorsi. The axilla is broad internally at the chest, but narrow and pointed externally at the arm. The **anterior boundary** is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part, the costo-coracoid membrane, the clavicle, and the Subclavius muscle. The **posterior boundary**, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the **inner side** are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the **outer side**, where the anterior and posterior boundaries converge, the space is narrow, and bounded by the humerus, the Coraco-brachialis and Biceps muscles.

**Contents.**—This space contains the axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

**Position of the Contents.**—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the forepart of the axillary space, in contact with the Pectoral muscles, and along the anterior margin are the thoracic branches of the axillary artery, and along the lower margin of the Pectoralis minor the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the outer border of this muscle is the dorsalis scapulae artery and veins; and, close to the neck of the humerus, the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation—viz., the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercosto-humeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue and a large number of small arteries and veins, all of which are, however, of inconsiderable size, and numerous lymphatic glands, the position and arrangement of which are described on a subsequent page.

**Surgical Anatomy.**—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or pus. The axilla may be the seat of rapidly growing tumors. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous abscesses and boils, and of eruptions due to irritation.

In **suppuration** in the axilla the arrangement of the fasciae plays a very important part in the direction which the pus takes. As described on page 464, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits
to enclose this muscle, and, reblanding at its lower border, becomes incorporated with the axillary fascia at the anterior fold of the axilla. This is known as the *clavipectoral fascia*. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorals or below the Pectoralis minor: in the former case, the pus would point either at the anterior border of the axillary fold or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the skin is prevented by the axillary fascia; its progress backward, by the Serratus magnus; forward, by the clavi-pectoral fascia; inward, by the wall of the thorax; and outward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an *axillary abscess* the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps after an incision has been made through the skin and fascia in the manner directed by the late Mr. Hilton.

The student should attentively consider the relation of the vessels and nerves in the several parts of the axilla, for it is the universal plan, at the present day, to remove the glands from the axilla in operating for *cancer of the breast*. In performing such an operation it will be necessary to proceed with much caution in the direction of the outer wall and apex of the space, as here the axillary vessels will be in danger of being wounded. Toward the posterior wall it will be necessary to avoid the subscapular, dorsalis scapulae, and posterior circumflex vessels. Along the anterior wall it will be necessary to avoid the thoracic branches. In clearing out the axilla the axillary vein should be first defined and cleared up to the apex of the axilla. When the apex of the space is reached, all fat and glands must be carefully removed and the whole axilla cleared by separating the tissues along the inner and posterior walls, so that when the proceeding is completed, the axilla is cleared of all its contents except the main vessels and nerves.

**THE AXILLARY ARTERY (A. AXILLARIS)** (Fig. 411).

The axillary artery, the continuation of the subclavian, commences at the outer border of the first rib, and terminates at the lower border of the tendon
of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: when the arm lies by the side of the chest, the vessel forms a gentle curve, the convexity being upward and outward; when the arm is directed at right angles with the trunk, the vessel is nearly straight; and when the arm is elevated still higher, the arteries describe a curve the concavity of which is directed upward. At its commencement the artery is very deeply situated, but near its termination it is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three portions, the first portion being above the Pectoralis minor; the second portion behind; and the third below that muscle.

**Relations.**—The **first portion** of the axillary artery is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the second and a portion of the third digitation of the Serratus magnus, and the posterior thoracic and internal anterior thoracic nerves; on its *outer side*, with the brachial plexus, from which it is separated by a little cellular interval; on its *inner* or thoracic side, with the axillary vein, which overlaps the artery.

**Relations of the First Portion of the Axillary Artery.**

*In front.*
- Pectoralis major.
- Costo-coracoid membrane.
- External anterior thoracic nerve.
- Acromio-thoracic and cephalic veins.

*Outer side.*
- Brachial plexus.

*Inner side.*
- Axillary Artery. First portion.
- Axillary vein.

*Behind.*
- First Intercostal space and Intercostal muscle.
- Second and third digitations of Serratus magnus.
- Posterior thoracic and Internal anterior thoracic nerves.

The **second portion** of the axillary artery lies beyond the Pectoralis minor. It is covered, *in front*, by the Pectoralis major and minor muscles; *behind*, it is separated from the Subscapularis by a cellular interval; on the *inner side* is the axillary vein, separated from the artery by the inner cord of the plexus and the internal anterior thoracic nerve. The brachial plexus of nerves surrounds the artery on three sides, and separates it from direct contact with the vein and adjacent muscles.

**Relations of the Second Portion of the Axillary Artery.**

*In front.*
- Pectoralis major and minor.

*Outer side.*
- Outer cord of plexus.

*Inner side.*
- Axillary vein.
- Inner cord of plexus.
- Internal anterior thoracic nerve.

*Behind.*
- Subscapularis.
- Posterior cord of plexus.
The third portion of the axillary artery lies below the Pectoralis minor. It is in relation, in front, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below, where it is crossed by the inner head of the median nerve; behind, with the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major; on its outer side, with the Coraco-brachialis; on its inner or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course: on the outer side is the median nerve, and the musculo-cutaneous for a short distance; on the inner side, the ulnar nerve (between the vein and artery) and the lesser internal cutaneous nerve (to the inner side of the vein); in front is the internal cutaneous nerve, and behind, the musculo-spiral and circumflex, the latter extending only to the lower border of the Subscapularis muscle.

Relations of the Third Portion of the Axillary Artery.

In front.
- Integument and fascia.
- Pectoralis major.
- Inner head of median nerve.
- Internal cutaneous nerve.

Outer side.

- Musculo-cutaneous nerve.

Inner side.
- Axillary nerve.
- Axillary vein.
- Lesser internal cutaneous nerve.

Behind.
- Subscapularis.
- Tendons of Latissimus dorsi and Teres major.
- Musculo-spiral and circumflex nerves.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm or a large muscular trunk. In the first set of cases this artery is most frequently the radial (1 in 33), sometimes the ulnar (1 in 72), and, very rarely, the interosseous (1 in 506). In the second set of cases the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes only one of the circumflex, or one of the profunda arteries, arose from the trunk. In these cases the brachial plexus surrounded the trunk of the branches and not the main vessel.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle with the body and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis muscle.

Surgical Anatomy.—The student, having carefully examined the relations of the axillary artery in its various parts, should now consider in what situation compression of this vessel may be most easily effected, and the best position for the application of a ligature to it when necessary.

Compression of the vessel may be required in the removal of tumors or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outward against the humerus the circulation may be effectually arrested.

The axillary artery is perhaps more frequently lacerated than any other artery in the body, with the exception of the popliteal, by violent movements of the extremity, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint. This accident is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having become fixed to the capsule of the joint. Aneurism of the axillary artery is of frequent occurrence, a large percentage of the cases being traumatic in their origin, due to the violence to which the vessel is exposed in the varied, extensive, and often violent movements of the limb.

The application of a ligature to the axillary artery may be required in cases of aneurism of the upper part of the brachial or as a distal operation for aneurism of the sub-
clavian; and there are only two situations in which the vessel can be secured—viz., in the first and in the third parts of its course; for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nerve trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the third part of its course the operation is most simple, and may be performed in the following manner: The patient being placed on a bed and the arm separated from the side, with the hand supinated, an incision about two inches in length is made through the integument forming the floor of the axilla, the cut being a little nearer to the anterior than the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed round the artery from the ulnar to the radial side.

This portion of the artery is occasionally crossed by a muscular slip, the axillary arch, derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscular fasciculus was spoken of in the description of the muscles. It may easily be recognized by the transverse direction of its fibres.

The first portion of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that in this situation it would be necessary to divide a thick muscle, and, after incising the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the vessel particularly hazardous. Under such circumstances it is an easier, and at the same time more advisable, operation to tie the subclavian artery in the third part of its course.

The vessel in the first part of its course can best be secured through a curved incision the convexity of which is downward. This incision passes from a point half an inch external to the sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and this incision is carried through the superficial structures, care being taken to avoid the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downward. The costo-coracoïd membrane is to be carefully divided close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

In a case of wound of the vessel the general practice of cutting down upon and tying it above and below the wounded point should be adopted in all cases.

**Collateral Circulation after Ligature of the Axillary Artery.**—If the artery be tied above the origin of the acromial thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromial thoracic and subscapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation, to which the long thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature be below the origin of the subscapular artery, it will most probably also be below the origins of the circumflex arteries. The chief agents in restoring the circulation will then be the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial, which will be afterward referred to as performing the same office after ligation of the brachial. The cases in which the operation has been performed are few in number, and no published account of dissections of the collateral circulation appears to exist.

**Branches.**—The branches of the axillary artery are—

From first part \{ Superior Thoracic.  
Acromial Thoracic. \}
From second part \{ Long Thoracic.  
Subscapular. \}
From third part \{ Posterior Circumflex.  
Anterior Circumflex. \}

The **Superior Thoracic** (a. thoracalis suprema) is a small artery which arises from the axillary separately or by a common trunk with the acromial thoracic. Running forward and inward along the upper border of the Pectoralis minor, it
passes between it and the Pectoralis major to the side of the chest. It supplies these muscles and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **Acromial Thoracic** or the **Thoracic Axis** (*a. thoracocromialis*) is a short trunk which *arises* from the forepart of the axillary artery, its origin being generally overlapped by the upper edge of the Pectoralis minor. Projecting forward to the upper border of the Pectoralis minor, it divides into four sets of branches—**thoracic**, **acromial**, **descending**, and **clavicular**.

The **Thoracic Branches** (*rami pectorales*), two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary.

The **Acromial Branch** (*ramus acromialis*) is directed outward toward the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries.

The **Descending** or **Humeral Branch** (*ramus deltoideus*) passes in the space between the Pectoralis major and Deltoid, in the same groove as the cephalic vein, and supplies both muscles.

The **Clavicular Branch** (*ramus clavicularis*), which is very small, passes upward to the Subclavius muscle.

The **Long Thoracic** or the **External Mammary** (*a. thoracalis lateralis*) passes downward and inward along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and **Subscapularis**; it anastomoses with the internal mammary and intercostal arteries.

The **Alar Thoracic** is a small branch which supplies the glands and areolar tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **Subscapular** (*a. subscapularis*), the largest branch of the axillary artery, *arises* opposite the lower border of the Subscapularis muscle, and passes downward and backward along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular, a branch of the transversalis colli, from the thyroid axis of the subclavian. About an inch and a half from its origin it gives off a large branch, the **dorsalis scapulae**, and terminates by supplying branches to the muscles in the neighborhood.

The **Dorsalis Scapulae** (*a. circumflexa scapulae*) is given off from the subscapular about an inch and a half from its origin, and is generally larger than the continuation of the vessel. It curves round the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (Fig. 409), and enters the infraspinous fossa by passing under cover of the Teres minor, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two sets of branches: one enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

The **Circumflex Arteries** wind round the surgical neck of the humerus. The **posterior circumflex** (*a. circumflexa humeri posterior*) (Fig. 409), the larger of the two, *arises* from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backward with the circumflex veins and nerve
through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds round the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The anterior circumflex (a. circumflexa humeri anterior) (Figs. 409 and 411), considerably smaller than the preceding, arises nearly opposite that vessel from the outer side of the axillary artery. It passes horizontally outward beneath the Coraco-brachialis and short head of the Biceps, lying upon the forepart of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upward along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outward beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

THE BRACHIAL ARTERY (A. BRACHIALIS) (Fig. 412).

The brachial artery (a. brachialis) commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the radial and ulnar arteries. At first the brachial artery lies internal to the humerus; but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two condyles.

Relations.—This artery is superficial throughout its entire extent, being covered, in front, by the integument, the superficial and deep fasciae; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle; behind, it is separated from the long head of the Triceps by the musculo-spiral nerve and superior profunda artery. It then lies upon the inner head of the Triceps, next upon the insertion of the Coraco-brachialis, and lastly on the Brachialis ante-
ticus; by its outer side, it is in relation with the commencement of the median nerve and the Coraco-brachialis and Biceps muscles, which overlap the artery to a considerable extent; by its inner side, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. The brachial artery is accompanied by
two veins comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

**Plan of the Relations of the Brachial Artery.**

*In front.*
- Integument and fasciae.
- Bicipital fascia, median basilic vein.
- Median nerve.
- Overlapped by Coraco-brachialis and Biceps.

**Outer side.**
- Median nerve (above).
- Coraco-brachialis.
- Biceps.

**Brachial Artery.**

**Inner side.**
- Internal cutaneous and Ulnar nerves.
- Median nerve (below).
- Basilic vein.

**Behind.**
- Triceps (long and inner heads).
- Musculo-spiral nerve.
- Superior profunda artery.
- Coraco-brachialis.
- Brachialis anticus.

**Surgical Anatomy of the Bend of the Elbow.**

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the antecubital space, the base of which is directed upward, and may be represented by a line connecting the two condyles of the humerus; the sides are bounded, externally, by the inner edge of the Supinator longus; internally, by the outer margin of the Pronator radii teres; its floor is formed by the Brachialis anticus and Supinator brevis. This space contains the brachial artery with its accompanying veins, the radial and ulnar arteries, the median and musculo-spiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, in front, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. Behind, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid origin of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, situated upon the Supinator brevis and partly concealed by the Supinator longus.

**Peculiarities of the Brachial Artery as Regards its Course.**—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps and descend toward the inner condyle of the humerus, where it usually curves round a prominence of bone, the supracondylar process. From this process, in most subjects, a fibrous arch is thrown over the artery. The vessel then inclines outward, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy to the normal condition of the artery in some of the carnivora: it has been referred to in the description of the humerus (page 180).

**As Regards its Division.**—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. "In 94 cases out of 481, or about 1 in 5⅓, there were two arteries instead of one in some part or in the whole of the arm."
There appears, however, to be no correspondence between the arteries of the two arms with respect to their irregular division; for in 61 bodies it occurred on one side only in 43; on both sides, in different positions, in 13; on both sides, in the same position, in 5.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature; under any of these circumstances two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high origin of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and accompanies that vessel to the lower part of the arm, and descends toward the inner condyle. In the forearm it generally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary; as it passes down the arm it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high origin of the radial the remaining trunk (ulnar interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outward, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited. Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

**Varieties in Muscular Relations.**—The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus, and Pronator radii teres muscles.

**Surface Marking.**—The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the junction of the anterior and middle thirds of the axillary outlet to the middle of the front of the elbow-joint.

**Surgical Anatomy.**—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward; and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front of the humerus below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

The application of a ligature to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibres is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

*In the upper third of the arm* the artery may be exposed in the following manner: The patient being placed supine upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axillary. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venue comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm in consequence of a high division, they are usually placed side by side: and if they are exposed in an operation, the surgeon should endeavor to

---

1 See Struthers's Anatomical and Physiological Observations.
ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hemorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk: a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied below the origin of the profunda arteries, the circulation is maintained by the branches of the profunda, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South, in which the brachial artery had been tied some time previously, in one "a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery."

Branches.—The branches of the brachial artery are—the

Superior Profunda. Inferior Profunda.
Nutrient. Anastomotica Magna.
Muscular.

The Superior Profunda Artery (a. profunda brachii) arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backward to the interval between the outer and inner heads of the Triceps muscle; accompanied by the musculo-spiral nerve it winds around the back part of the shaft of the humerus in the spiral groove, between the outer head of the Triceps and the bone, to the outer side of the humerus, where it reaches the external intermuscular septum and divides into two terminal branches. One of these pierces the external intermuscular septum, and descends, in company with the musculo- spiral nerve, to the space between the Brachialis anticus and Supinator longus, where it anastomoses with the recurrent branch of the radial artery; while the other, much the larger of the two, descends along the back of the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (Fig. 415). The superior profunda supplies the Triceps muscle and gives off a nutrient artery which enters the bone at the upper end of the musculo-spiral groove. Near its commencement it sends off a branch which passes upward between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex

1 Chelius’s Surgery, vol. ii. p. 254. See also White’s engravings, referred to by Mr. South, of the anastomosing branches after ligation of the brachial, in White’s Cases in Surgery. Porta also gives a case (with drawings) of the circulation after ligation of both brachial and radial (Alterazioni Patologiche delle Arterie).—Ed. of 15th English edition.
artery, and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

The **Nutrient Artery** (*a. nutricia humeri*) of the shaft of the humerus *arises* from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the Coraco-brachialis muscle.

The **Inferior Profunda** (*a. collateralis ulnaris superior*), of small size, *arises* from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It sometimes supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The **Anastomotica Magna** (*a. collateralis ulnaris inferior*) *arises* from the brachial about two inches above the elbow-joint. It passes transversely inward upon the Brachialis aniceps, and, piercing the internal intermuscular septum, winds round the back of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis aniceps, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

The **Muscular** (*rami musculares*) are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis aniceps muscles.
The Anastomosis around the Elbow-joint (Fig. 415).—The vessels engaged in this anastomosis may be conveniently divided into those situated in front and behind the internal and external condyles. The branches anastomosing in front of the internal condyle are the anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those behind the internal condyle are the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing in front of the external condyle are the radial recurrent and the anterior terminal branch of the superior profunda. Those behind the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the anastomotica magna, the interosseous recurrent, and the posterior terminal branch of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the anastomotica magna and posterior ulnar recurrent.

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that in front of the external condyle.

The Radial Artery (A. Radialis) (Figs. 413, 414).

The radial artery appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backward, round the outer side of the carpus, beneath the extensor tendons of the thumb, to the upper end of the space between the metacarpal bones of the thumb and index finger, and finally passes forward, between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination it inosculates with the deep branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz., in the forearm, at the back of the wrist, and in the hand.

Relations.—In the forearm this vessel extends from opposite the neck of the radius to the forepart of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Supinator longus muscle; throughout the rest of its course it is superficial, being covered by the integument, the superficial and deep fasciae. In its course downward it lies upon the tendon of the Biceps, the Supinator brevis, the Pronator radii teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Supinator longus and the Pronator radii teres; in the lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies close to the outer side of the artery in the middle third of its course, and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venae comites throughout its whole course.

At the wrist, as it winds round the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculo-cutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseus muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it inosculates with the communicating branch from the ulnar artery, forming the deep palmar arch.

The Deep Palmar Arch (arcus volaris profundus) (Fig. 414).—It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor brevis minimi digiti. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction; that is to say, from within outward. The branches of the deep palmar arch are the palmar interosseous, perforating and palmar recurrent vessels (page 660).

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of under its inner border; and in turning round the wrist it has been seen lying over, instead of beneath, the extensor tendons of the thumb.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the forepart of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and similar accidents. The injury is often followed by a traumatic aneurism, for which the operation of extirpating or laying open the sac after securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Supinator longus drawn a little outward, the artery will be exposed. The venae comites should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.
Branches (Figs. 413, 414, and 415).—The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

The Radial Recurrent (a. recurrens radialis) (Fig. 414) is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with the terminal branches of the superior profunda.

The Muscular Branches (rami musculares) are distributed to the muscles on the radial side of the forearm.

The Anterior Radial Carpal (ramus carpeus volaris) (Fig. 414) is a small vessel which arises from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, the anterior carpal arch (rete carpi volare), is formed in front of the wrist; it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep palmar arch below, and gives off branches which descend to supply the articulations of the wrist and carpus.

The Superficialis Vole (ramus volaris superficialis) (Fig. 414) arises from the radial artery, just where this vessel is about to wind round the wrist. Running forward, it passes between, occasionally over, the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size: usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The Posterior Radial Carpal (ramus carpeus dorsalis) (Fig. 415) is a small vessel which arises from the radial artery beneath the extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the posterior carpal arch (rete carpi dorsale), which is joined by the termination of the anterior interosseous artery. From this arch are given off descending branches, the dorsal interosseous arteries (aa. metacarpae dorsales) for the second, third, and fourth interosseous spaces, which run forward on the Second, Third, and Fourth dorsal interossei muscles, and divide into dorsal digital branches (aa. digitales dorsales), which supply the adjacent sides of the index, middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. The dorsal interosseous arteries anastomose with the perforating branches from the deep palmar arch (rami perforantes).

The Dorsales Pollicis (Fig. 415) are two vessels which run along the sides of the dorsal aspect of the thumb. They arise separately, or occasionally by a common trunk, near the base of the first metacarpal bone.

The Dorsalis Indicis (Fig. 415), also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.
The **Princps Pollicis** (*a. princeps pollicis*) (Fig. 414) arises from the radial just as it turns inward to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it divides into two branches, which run along the sides of the palmar aspect of the thumb, and form an arch on the palmar surface of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

The **Radialis Indicis** (*a. volaris indicis radialis*) (Fig. 414) arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The **Perforating Arteries** (*rami perforantes*) (Fig. 414), three in number, pass backward from the deep palmar arch between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The **Palmar Interosseous** (*aa. metacarpae volares*) (Fig. 414), three or four in number, arise from the convexity of the deep palmar arch; they run forward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The **Palmar Recurrent Branches** arise from the concavity of the deep palmar arch. They pass upward in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

**The Ulnar Artery** (*A. Ulnaris*) (Figs. 413, 414).

The ulnar artery, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the
inner side of the forearm to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches which enter into the formation of the superficial and deep palmar arches.

Relations. In the Forearm.—In its upper half it is deeply seated, being covered by all the superficial Flexor muscles, excepting the Flexor carpi ulnaris; the median nerve is in relation with the inner side of the artery for about an inch and then crosses the vessel, being separated from it by the deep head of the Pronator radii teres; it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the lower half of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciae, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

At the wrist (Fig. 413) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery; here the nerve and artery are crossed by a band of fibres, which extends from the pisiform bone to the anterior annular ligament.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source or origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the Flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the antecubital space to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Surgical Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side.
of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside. Some little distance below the nerve the artery will be found accompanied by its vena comites, and it may be ligatured by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its vena comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

Branches (Figs. 413, 414, and 415).—The branches of the ulnar artery may be arranged in the following groups:
